1926

SUPPLEMENT.

THE INDIAN MEDICAL YEAR, 1925.*

In presenting this review of the Indian medical year, 1925, the reviewer would like to express his most sincere and grateful thanks to the distinguished contributors who have helped to make it a symposium by several different writers, rather than a review by a single author.

DISEASES OF THE TROPICS, EPIDEMIOLOGY, SYMPTOMATOLOGY AND TREATMENT.

MALARIA.

Perhaps the most important event of the year in connection with malaria, as the gravest of all public health problems in India, was the discussion at the Conference of Medical Research Workers held at Calcutta in December. The "Central Malaria Bureau" for all-India at present consists of one small room at the Central Research Institute, Kasauli, some 180 feet square, with a staff of one officer—part-time, one sub-assistant surgeon, one peon and one sweeper. Colonel Christophers described the (imaginary) visit to this bureau of some American familiar with Rockefeller methods in the investigation and control of diseases in the tropics. His remark would probably be "Is this the 'Central Malaria Bureau' for all-India?" A resolution was unanimously passed strongly supporting Colonel Christophers' recommendations for (a) immediate and temporary measures to expand the dimensions and activities and staff of the bureau, and (b) for future provision of a fully staffed and equipped institute and bureau, commensurate with the immense needs of India; a scheme which may require sanction by the Secretary of State, and probably some addition to the cadre of the Medical Research Department.

Epidemiology.—The visit of Sir Malcolm Watson to the infected areas in the Assam tea gardens is the outstanding event of the year. We have previously dealt with Sir Malcolm Watson's wonderful work in Malaya in our columns; work with results almost equal to those achieved by the Americans in Panama, and the more remarkable in that he had not only to deal with severe epidemic malaria in the F. M. S., but—unlike the Americans—had to persuade the rubber companies concerned that the control of malaria is a paying proposition in hard cash. It can no longer be said that the great industries of India are not alive to this problem; the tea and coal mining industries for instance, have taken vigorous steps to deal with it; and the present trouble is not want of funds, but of trained investigators to carry out the much-needed surveys. Dr. C. Strickland, working on a special grant from the Indian Tea Association since 1923; has been investigating the position in general in connection with the tea industry in Assam, and his results were presented

in a paper read before the annual meeting in March, 1925, of the Assam Branch of the British Medical Association, and in a paper in our issue for November. Haphazard methods for mosquito control, he claims, are useless; the advantages of a survey are (a) to locate healthy sites for bungalows and lines; (b) to localise the area within which anti-mosquito measures should be taken, and (c) to choose the most appropriate measures for the actual problem in hand. Thus, to drain a swamp to eradicate *A. umbrosus*—an important carrier in Assam—may but mean the introduction of *A. maculatus*, which breeds in clear running streams and is an even worse carrier. The important carrying species in Assam are (a) *A. umbrosus*; found at Baliapara and probably of widespread incidence in Assam. This mosquito can be eliminated by clearing out all jungle within 300 yards' radius of lines; (b) *A. maculatus*, as incriminated in the surveys at Pasighat and Lumding, also by Malcolm Watson at Doom Dooma; (c) *A. culicifacies*, a clean water breeder, especially prevalent with the advent of the rains; and (d) *A. funestus*. Bungalows and club houses—especially—should be screened. Water tidiness in general is necessary, and is of special value against *A. maculatus* and *minimus*; oiling of pools is of value against *A. culicifacies*; whilst controlled flooding should be used more than it is. In certain places jungle growth should be encouraged in *hulas* and *hals*, after draining them, against *A. maculatus* and *umbrosus*, in other areas jungle should be cleared to get rid of other carrying species. "Save the women and children" from malaria on the tea estates, and the labour population will be contented and happy; what the women of India think to-day, the men think to-morrow. Anti-malarial measures, based upon a survey of the local problems, have succeeded in Malaya; there is no reason why measures based upon the results of similar surveys in Assam should not succeed.

The same author criticises Dr. C. A. Bentley's "Malaria and Agriculture in Bengal." Dr. Bentley claims that epidemic malaria in Bengal is due primarily to the embanking of the land, which prevents the natural flood and flush of the Gangetic delta area. Dr. Strickland considers that if there was not a single embankment in Bengal, its malarial incidence would still be much as it is at present. Dr. Bentley suggests, by way of control, "bonification"—the Italian method of controlled flooding and flushing; but Dr. Strickland considers that this will not affect *A. aconitus* and *A. funestus* (*minimus*), which are important carriers in Bengal. In general, however, he supports Dr. Bentley's policy of controlled irrigation for the malarious districts of Bengal.

Lieutenant-Colonel C. A. Gill comments on the possible rôle of *A. rossii* as a carrier of malaria. It is the commonest anopheline of India, and from July to October swarms in every portion of the rural areas in the Punjab, outnumbering all other anophelines present put together. Even if it be but a poor carrier of malaria, yet it is so prevalent that it might be responsible for much malaria. Under laboratory conditions it can be infected experimentally with *P. vivax*, and shews sporozoites in its salivary glands, whereas it failed to take with *P. falciparum*. It is an avid sucker of human blood, and—upon applying the precipitin test to the blood-meal within its mid-gut—has been found to feed by preference upon man, even in the presence of cattle. The literature upon the subject is very confused. Is it possible that *A. rossii* is a carrier in the Punjab of *P. vivax*, though not of *P. falciparum* infections?

Mr. R. Senior-White, F.R.S., records the eradication of malaria from a rubber estate in Ceylon with a total population of 357 souls. From 1914 to 1921 malaria cost the estate approximately Rs. 831 per annum in loss of working days, and the population of 357 shewed an annual average of 830 admissions to hospital for malaria. The expenditure upon prophylactic quinine was Rs. 352 per annum. In 1919

*Notes.—(1) Unless otherwise stated, the commissioned officers referred to are all officers of the Indian Medical Service. In order to save space, references to qualifications, decorations and titles have been omitted.

(2) In compiling this review some 15 journals for 1925 have been studied and all papers of importance by workers in India abstracted. The reviewer trusts that the resulting review is fairly comprehensive, but does not guarantee that it includes references to all work published by writers in India during the year. A bibliography of references would have been a desirable addition; but considerations of space forbid this.

(3) Extra copies of this review are available from Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta, at a cost of Re. 1 each.

a survey was carried out, and *A. maculatus* incriminated. Its breeding places were thoroughly dealt with, chiefly by oiling, at a cost of Rs. 195 per annum. The annual average number of deaths from malaria dropped from 13 to 4, with an estimated saving of Rs. 480 per annum on increased number of days' work. The example is a small one, but it is typical of results which can be multiplied almost indefinitely upon a much larger scale.

In our last annual review we commented upon the very valuable malarial survey of the Singbhum mining settlements by Colonel Christophers; this report has now been re-published in the *Indian Journal of Medical Research* for October, 1925, and will thus fortunately reach a much wider circle of readers. Colonel Christophers' survey has been continued by Captain R. C. Watts. In the Bengal Iron Co.'s settlements at Manoharpur, Chiria and Duia, *A. culicifacies* was incriminated as the most important carrier; the spleen rates being respectively, 81 per cent., 57 per cent., and 67 per cent. At Manoharpur the local ravine should be drained, a pestilential rice field cleared, and the railway excavations dealt with. At Chiria the camp site should be moved to the adjacent Buda hill, and bungalows screened; here there were 638 admissions for malaria in three months, August to October, 1923, from among a labour force of 1,441. At the Cape Copper Co.'s mines at Bakha the tank should be abolished, an adjacent rice field purchased and dealt with, and the copper sulphate discharge from the main shaft diverted up-stream in order to kill mosquito larvæ. At Chiria of 300 imported Madrassi coolies at one mine, 10 were dead from cerebral malaria within a fortnight of arrival, and the rest decamped. Throughout the enquiry *P. tenue* forms were the chief type of parasite encountered. Such commercial enterprises would do well to consult a medical or health officer before selecting sites for bungalows and lines; jungle should be cleared for at least 200 yards around camps, and any distance within quarter of a mile of rice cultivation avoided. Prophylactic quinine and mosquito brigades are also advocated.

Drs. J. Dodds Price and C. Strickland deal with the significance of the splenic index for malaria in endemic kala-azar areas. Rare pathological causes of splenic enlargement need not be considered; but kala-azar is of importance when clinical signs of the disease are well marked. Where clinical evidence of kala-azar is not marked, the degree of splenomegaly of the community may be taken as an index of malarial incidence. Should clinically evident kala-azar be present, splenic indices should be controlled by observations of the endemic (parasitic) malarial index.

Dr. D. A. Turkhud, writing from the King Institute of Preventive Medicine, Guindy, Madras, notes that malarial surveys were carried out during the year by the mobile epidemic units attached to the Institute in the districts of Ennore, Vayalur, Mettur, Vizagapatam and Simhachellam. Ennore was found to be a hyper-endemic focus, whence the infection travelled to other areas. *A. culicifacies* and *A. fuliginosus* were the chief carriers. Work in connection with the Mettur and Vizagapatam areas is still in progress, this work being of extreme importance in view of the official decision to create a new, large harbour for ocean-going vessels at the latter port. The area is intensely malarious, the chief anopheline carriers being *A. culicifacies*, *fuliginosus*, *stephensi*, *barbirostris*, and *minimus*. Spleen rates vary from 50 to 85 per cent., and parasite rates from 60 to 93 per cent. Simhachellam is a small hill station in the area which is a pilgrim centre; the spleen rate is from 70 to 85 per cent. and *A. fuliginosus* is the chief carrier. Recommendations are being made to deal with each area concerned.

It will be seen that, although—as Colonel Cunningham complained at the Medical Research Workers' Conference in Calcutta in December—at the 1925 conference of different nations at Rome on malarial problems and epidemiology, no reference was made to the work of

workers in India, yet the malarial problems of India are not without attention. The reproach that India has made less use of Sir Ronald Ross' great discovery than any other country is not deserved; it is all a question of men and money.

Clinical.—Numerous papers on the clinical aspects of malaria have appeared during the year in India. The very complete discussion on the use of the different alkaloids of cinchona febrifuge at the January, 1925 meeting of the Royal Society of Tropical Medicine and Hygiene, by Colonel Clayton Lane and Colonel Gage, amongst others, has already been fully reviewed in our issue for last January, p. 30.

R. B. Lal discusses the relative proportion of male and female crescents in malignant tertian infections; from September 25th to December 17th, in a series of continuously observed cases, the proportion was about equal. During the subsequent winter months, however, the proportion of female crescents appeared to decline steadily.

In the treatment of malaria, K. V. Raju describes the value of Sinton's combined alkali plus quinine method. The method is more suitable for in-patients than for out-patients. The mixtures are well tolerated: patients once treated have not returned to hospital with relapses; and after the administration of from 20 to 40 grains of quinine by this method the patients are almost always afebrile. K. Majumdar records the case of a child of 5, with a temperature of 106°F., stoppage of respiration and apparent death. Plunging into a cold tub, artificial respiration, and a daily dose of 5 grains of quinine bishydrochloride intramuscularly brought about recovery. N. Ghosh records a case of cerebral malaria with sudden onset, convulsions and a sub-normal temperature. Intravenous administration of quinine bishydrochloride in 8 gr. doses with $\frac{1}{2}$ c.c. doses of pituitrin saved life. K. N. Chatterji records a case of a young boy almost pulseless on the fifth day of fever, with vomiting, purging and hemorrhagic stools with agonising abdominal pain. Quinine bishydrochloride, gr. 5 in 10 c.c. of saline was given intravenously plus an injection of 10 m. of adrenalin solution, and repeated next day. The patient made a complete recovery. V. N. Deuskar comments on an unusual case with severe recurrent urticaria and very severe abdominal colic at times of rigor as the chief symptoms. J. Dhairyam deals with the treatment of malaria in pregnancy. The treatment advocated is (a) a preliminary purge of calomel or castor oil; (b) half an hour later 10 grs. of quinine acid hydrochloride intramuscularly with 10 grs. of potassium bromide by the mouth; (c) half an hour later repeat the same dose of potassium bromide. This course of treatment is repeated on the next day; and from the third day onwards 10-gr. doses of quinine are given by the mouth, followed by 7-gr. doses of potassium bromide, both t.d.s. Dr. T. H. Bishop describes the value of routine cinchona febrifuge mixture as a prophylactic on the E. B. Railway.

Of drugs other than quinine, Dr. A. Neave Kingsbury and K. Kanagarayer have tested "mercurochrome, 220," a 5 per cent. solution given intravenously in 20 c.c. doses; they found it quite useless both in benign tertian and malignant tertian infections, and its use attended with such unpleasant sequelæ as stomatitis. Dr. W. Fletcher of the Kuala Lumpur Institute has tested "Peracrina, 303." He considers that it appears to consist of yeast cells plus a little starch and a yellow dye—presumably acriflavine. It proved impracticable to administer it for a long period and in the large doses recommended by the makers. It is far too expensive for general use—a single full course of treatment costing about £2-16-0. It appeared to have no effect whatever upon the malarial parasites upon trial in 18 patients, duly controlled by blood examinations. In some instances its administration was attended by such severe exacerbation of the malaria that it had to be suspended and quinine given in its place.

In connection with *blackwater fever*, Dr. U. N. Brahmachari and P. B. Sen record an investigation into the mechanism of quinine hæmoglobinæmia in man. The history is given of a patient who suffered from hæmoglobinuria one to two hours after each of four doses, of 5 grains of quinine. No malarial parasites could be detected upon repeated examination of thick and thin blood films. The patient's red blood corpuscles were *not* more fragile than normal, nor was his serum hæmolytic to normal erythrocytes. No hæmolysin could be demonstrated in his serum after quinine administration. The patient was suffering from kala-azar also; this was cured by urea stibamine, but cure of the kala-azar did not affect the spontaneous tendency to hæmoglobinuria on quinine administration.

Apart from true malaria, Captain W. C. Spackman draws attention to the occurrence of Gaucher's type of splenomegaly in the Mahratta village of Dhagur, near Nasik. The village used to have a population of 400 souls; it is now deserted by reason of a curious epidemic outbreak of splenomegaly, which caused 12 cases in 3 families, and shewed a very marked familial incidence. It was confined to the Mahrattas, the Kolis and Chamars living in the same village being unaffected. In one patient, aged 16, splenectomy was resorted to with apparent recovery. Lieutenant-Colonel F. P. Mackie reports on this spleen that no *Leishmania* parasites could be found, and sections shewed great reduction of the lymphoid tissue of the spleen with endothelial overgrowth; thus corresponding to Gaucher's type of splenomegaly. J. N. Sen records an interesting case of enlarged and wandering spleen mistaken for ovarian tumour, with splenectomy and recovery; the removed spleen was malarial and weighed 4 lbs. 12 ozs.

PLAGUE.

Major W. D. H. Stevenson and Khan Bahadur R. J. Kapadia shew that there is complete absence of the usual phenomenon of a negative phase in immunity after inoculation with Haffkine's vaccine. Production of immunity in inoculated rats commences within a few hours of inoculation and increases in amount till the second or third day; after 14 days a considerable degree of immunity is still present in these rats. Captain R. H. Malone, Khan Bahadur C. R. Avari and B. P. B. Naidu have studied the bactericidal power of rats' blood as a measure of their immunity to plague, and shew that a definite correlation exists. Two per cent. of natural Madras rats, 33 per cent. of Bombay rats, and 97 per cent. of immunised Madras rats were found to be insusceptible to infection; tissue-immunity is probably a factor in producing these results; and it may be possible to assess the immunity in man by tests of the bactericidal power of the blood. More light is needed upon the mechanism of natural and acquired immunity to plague.

Dr. J. Balfour Kirk from Mauritius records a fatal case of bubonic plague with a small-pox like rash. From the sixth day of illness onwards a discrete papular rash appeared in successive crops on the face, neck, arms, buttocks and thighs; it became maculopustular and then pustular. There was no itching. Pus collected from two of the pustules under full aseptic precautions yielded cultures of *B. pestis*. The patient died on the 19th day of illness.

By way of prophylaxis, the studies in 1925 by R. B. Lal and C. D. Tiwari of methods of disinfection deserve attention. Cresol fumigation as ordinarily carried out has no action on rats, but has a definite action on rat fleas, household furniture and rat runs affording protection to the rats against the fumes. The toxic action of cresol vapour tends to be more manifest at higher levels within the room. In actual use therefore all furniture, etc., should be removed from the room before cresol is used. At least 10 ozs. of cresol should be used per 1,000 cubic feet of space. The drug is best distributed over two pans containing smouldering cow-dung; the room should be carefully

sealed before fumigation, the floor subsequently washed with phenyl, and rat runs subsequently dealt with by *neem battis*. The same authors deal with fumigation with *neem battis*, and find that this measure will kill rats and their fleas in burrows in the fields in five minutes, if the burrows be closed. The preparation of *neem battis* is as follows:—Potassium chlorate 2 drs.; potassium nitrate 1½ drs., and powdered sulphur are mixed together and mixed with 5 drs. of mustard or castor oil to form a paste. One drm. of chilli powder (red pepper) is added and a handful of dried *neem* leaves. Nine inch wicks of khadder cloth are taken and soaked in saturated potassium chlorate solution; the prepared paste is then spread thickly over the wicks, leaving the terminal inch free for lighting; and they are then finally wrapped in cloth and thick paper. The rat runs are closed at all entries and exits with one exception, a prepared *neem batti* lighted and inserted, and the final aperture then closed. The method will completely rid a given area of rats.

CHOLERA.

Epidemiology.—Perhaps the chief paper of the year is that by Lieutenant-Colonel A. B. Fry in our issue for July. The Public Health Committee of the League of Nations having put forward certain questions to India for answer, Colonel Fry attempts to answer them. Thus it must be admitted that India is still the endemic focus of epidemic cholera for the whole world, and that deltaic Bengal is still its endemic home in India where endemic cholera still occurs as regularly and as severely as ever. There is considerable evidence to shew that cholera in the rest of India is dependent upon the chronic cholera focus in Bengal; in the records of the nineteenth century it is easy to trace the spread of wave after wave of epidemic cholera from Bengal over India, and even as far as the banks of the Mississippi, but in the twentieth century the increased facilities for railway and rapid travel rather obscure the records. Why deltaic Bengal should thus constitute the endemic focus of cholera for the whole world deserves investigation; climatic, humidity, temperature and other factors affecting the viability of the vibrio are probably concerned. A concentrated attack upon this age-old focus for the whole world might be attended with the maximum of results; in the meantime stringent quarantine at ports and frontiers is obviously necessary. That deltaic Bengal is the chief cholera focus for the whole world is probable; what we propose to do about it is less evident, but the problem is not being neglected by the Indian Research Fund Association.

Major A. J. H. Russell has made an extensive study of the incidence of epidemic cholera in Madras Presidency, assisted by a grant from the Indian Research Fund Association. His results are reported both in the *Lancet* and elsewhere. Cholera in Madras Presidency—also in Bombay, the Punjab, United Provinces, and Central Provinces, when studied over the period 1896-1923 shews a remarkable six-year cycle of maximal periodicity. Colonel W. G. King (retd.) in a letter to the *Lancet* points out that he drew attention to this as long ago as 1894, and described a "Madras cholera clock." Importation into Madras in any period other than that following the chief monsoon period is not dangerous; the epidemic fizzles out. Colonel King's cholera clock has now kept good time for over 25 years. In Madras the endemic foci are found in the riverine and deltaic areas. In the northern area epidemic cholera sets in with the onset of the S. W. monsoon; in the southern area it breaks out six weeks to two months after the onset of the N. E. monsoon. The central areas shew two cholera peaks of incidence, roughly coinciding with the two chief peaks of rainfall. An annual periodic curve is shewn by Major Russell, together with a super-imposed more or less regular six-year cycle. He comments upon the great value of such fore-knowledge of the

periodicity of epidemic cholera in taking measures beforehand to control cholera epidemics.

Diagnosis.—Working in the Jheria coal-fields, Captain G. C. Maitra draws attention to the co-existence of two different conditions: (a) a cholera-like disease of indefinite aetiology, low infectivity and non-epidemicity; and (b) true cholera, introduced from the pilgrim centres at Puri and Baidyanath, and due to Koch's vibrio. Only competent bacteriological examination will differentiate between the two, and in the case of the former elaborate anti-cholera measures are not called for. The value of oral vaccination by Besredka's method is on trial. The examination of the cellular content of the stools microscopically in suspected cholera is of value in diagnosis. In 495 cases comma-like vibrios were found in 84 per cent.; 92 per cent. shewed evidence of concentration of the blood; whilst abundant presence of desquamated epithelial cells in the dejecta together with relative absence of polymorphonuclear leucocytes—in contra-distinction to what one finds in acute bacillary dysentery—is the rule. A cytological diagnosis can be returned in some 90 per cent. of cases. The same author, with J. B. Basu, has also studied 746 clinical cases of cholera admitted to the cholera wards of the Campbell Hospital, Calcutta. Here they find a complete contrast to conditions in the coal-fields. Over 90 per cent. of cases shewed true cholera vibrios or allied vibrios; which were present in 590 of the patients examined. No cholera-like outbreak of indeterminate aetiology was noticed.

Treatment.—Lieutenant-Colonel F. J. Palmer, R.A.M.C. (retd.), advocates the use of cresol. For an adult his formula is:—cresol m. 4; acidi sulphurici aromatici m. 5; water to 4 ozs.; as one dose; graduated for younger patients according to age. Of this 8 doses are given every quarter of an hour at first; then 4 doses at half-hourly intervals; then omit the acid and continue at 1 hourly intervals for 12 doses; finally at 2 and 3 hourly intervals. Nine cases treated are recorded, 8 of them in the collapse stage, with 7 recoveries. L. B. Ganguli records the trial of this treatment at the Campbell Hospital, Calcutta, from January to May, 1925, during the epidemic season. Group (a) of patients received calomel in fractional doses, with intravenous salines and alkalis. Group (b) received the cresol treatment, in the form of 'Izal' with intravenous saline but no alkalis. The total number treated was 513; divided into two groups of approximately equal numbers. The mortality in the two groups proved about identical, but in some of the Izal patients, the Izal treatment had to be suspended on account of threatened uræmia, and it is pointed out that these cresol derivatives are renal irritants. The standard rate of recovery at the Campbell Hospital under treatment by hypertonic salines and alkalis is about 80 per cent.

DYSENTERY AND AMOEBIASIS.

At the annual meeting of the Assam Branch of the British Medical Association, Dr. G. C. Ramsay drew attention to the exceedingly unsatisfactory state of affairs with regard to anti-dysenteric serum in India. Some five-sixths or more of the dysentery of India is bacillary in character and the specific or polyvalent serum is the best remedy. "It is inconceivable at this stage of civilization in India that all our anti-serum is imported from Great Britain, America, France and Japan. When we obtain our supplies from Shillong or Kasauli we are well aware that they have been kept in cold storage, but it would be instructive to know if these requirements are duly carried out by retail chemists in India. Perhaps this may explain the inertness of many samples." This is a problem to which we have often reverted in our columns; surely it should not be beyond the capacity of one of the many large vaccine and serum institutes in India to work out local strains, manufacture locally-made serum, and place satisfactory supplies at the disposal of the profession in India.

Captain G. R. McRobert deals with the abuse of emetine. The practice of "in diarrhoea try the effect of emetine," and "try emetine for all patients with liver disturbance" leads to disastrous results. Emetine is especially abused in military practice in this country. The treatment of every case of dysentery should be based upon an accurate microscopical diagnosis of the type of dysentery present; and in this connection the use of warmed cigarette tins, surrounded by a hot-water jacket, in which to send faecal samples to the laboratory is advocated. He has known patients undergoing courses of emetine treatment even to be permitted to enter as competitors for athletic events; it is no wonder that they "felt like death." Post-emetine toxæmia is not an infrequent sequel of bacillary dysentery in this country. Emetine is far too valuable a drug to be misused; in its right place it is incomparable.

Dr. D. A. Turkhud, Director of the King Institute of Preventive Medicine, Guindy, Madras, reports on an enquiry made at the Madras Penitentiary on the increasing admission rate for dysentery amongst the prisoners. Colonel Cunningham's method of daily macroscopic inspection of the stools of all convicts for ten days was carried out. Out of 903 convicts in the penitentiary, the stools of 700 were daily examined and 172 of these were separated as latent dysentery carriers and placed in a separate gang. Bacteriological examination of these cases detected 15 active carriers of *B. dysenteriae*—Flexner, Shiga and Morgan strains all being isolated. In addition there were 12 cases of *E. histolytica* infection. Ten convicts out of 26 employed in the kitchen were found to be dysentery carriers. The appropriate measures were taken and it is proposed to repeat such special examinations every six months in order to control the outbreaks.

An interesting paper by Assistant Surgeon B. M. Das Gupta deals with the vexed question of the identity or otherwise of *E. nuttalli* of the monkey with *E. histolytica* of man. A *Macacus rhesus* monkey was found dying of spontaneous dysentery and its stools shewed sluggishly motile entamoeba. These were cultured by Boeck and Drbohlav's technique, and grew well in culture. In culture the parasites were morphologically identical with *E. histolytica* and shewed ingested red blood corpuscles; but on injection into kittens no dysentery resulted. The same author has now repeatedly grown *E. histolytica* of man by the same technique, and it seems highly probable that in a year or two the test for protozoal infections of the intestine will be by cultural methods rather than by direct microscopical examination of the stools.

Lieutenant J. P. Arland records a case of liver abscess which proved fatal at operation. Two-thirds of the liver tissue was found to be destroyed and two pints of pus were evacuated from the liver. Death on the operation table was apparently due to the sudden relief of pressure on the inferior vena cava setting up a suction action on the heart. At post-mortem the heart and great vessels were found almost empty of blood. (In the reviewer's opinion, the only indication for open operation in the case of amœbic abscess of the liver is the presence of secondary sepsis or of urgent pressure symptoms; emetine plus aspiration is the standard line of treatment to-day, and one can scarcely ask for any better line of treatment; even the aspiration can often be dispensed with.) In connection with liver necrosis, Y. S. Row records the occurrence in four years in Alipuram jail of three cases of what was apparently acute yellow atrophy of the liver, without apparent cause, the aetiology of which was obscure.

ENTERIC FEVER.

Dr. W. Fletcher and J. E. Lesslar record an interesting case of typhoid septicaemia without typhoid ulcers in an old Chinaman in Kuala Lumpur. The patient died six weeks after the onset of illness. Two strains of *B. typhosus*, the one smooth and agglutinable, the

other rough and non-agglutinable, were isolated from his blood during life; the Flexner dysentery bacillus was isolated from his stools on each of the four occasions on which they were examined; at post-mortem *B. typhosus* was again isolated, this time from the gall-bladder; but there was no ulceration of the small intestine, only two old pigmented scars just above the ileocaecal valve. The patient may have been a chronic typhoid carrier suffering from bacillary dysentery.

A. B. de Castro records parotid abscess and fatal abscess of the spleen as sequelae of typhoid fever in two patients, whilst A. T. Roy describes the case of a Hindu girl of 12 who shewed extraordinary and persistent choreiform symptoms at the end of the third week of an attack of typhoid fever; these were associated with extreme constipation and a family history of nervous instability.

KALA-AZAR.

Dr. L. E. Napier, Kala-azar Research Worker, Calcutta School of Tropical Medicine, reviews the year as follows:—

"The kala-azar transmission problem. The most important work in connection with the kala-azar transmission problem is that carried out by the Kala-azar Commission and the Kala-azar Enquiry at the Calcutta School of Tropical Medicine.

At the end of 1924, Major R. Knowles, L. E. Napier and R. A. O. Smith first shewed that *L. donovani*, the causative organism of kala-azar, passes into its flagellate stage in the gut of the sandfly, *P. argentipes*, under suitable conditions of atmospheric temperature and humidity; out of 56 laboratory-bred flies fed on the blood of kala-azar cases 25 were shewn on dissection to contain flagellates, but 46 other flies similarly fed on patients not suffering from kala-azar did not shew any flagellates. In a subsequent paper Napier and Smith gave their experience of the development of the flagellates in the gut of the fly at different periods of the year; out of 674 fed flies dissected, 100 shewed flagellates in the 3rd to 5th days. Their investigation suggested that most of, but not all, the parasites ingested by the sandfly developed into flagellates. In parallel feeding experiments carried out with *P. papatasi*, no development was observed to take place. Attempts made by them to infect the second generation of flies by feeding the larvæ on infected adult flies apparently failed; 24 larvæ and 132 adult flies thus fed were dissected but no recognisable forms of *Leishmania* were observed.

In the study of the bionomics of the sandfly, *P. argentipes*, Napier and Smith report that this fly is to be found in Calcutta and the surrounding rural areas throughout the whole year; the numbers are observed to decrease during the cold weather months, December and January, and the driest months, April and May; the flies were caught in the ground-floor rooms of houses and huts but the largest numbers were observed in unpaved cowsheds. Large numbers of flies were caught during the period covered by this paper and were placed in breeding cages; from these 8,794 flies were bred out by the method devised by Dr. Smith and reported during the year.

In a serological investigation of the blood-meal of *P. argentipes*, Major R. B. Lloyd and Drs. Napier and Smith shewed that this sandfly feeds on the cow in preference to man, but on man in preference to other domestic animals, that therefore the presence of a cow protects man from the bite of the sandfly and that the cow might thus possibly play a part in the prophylaxis against kala-azar.

The Kala-azar Commission, consisting of Lieutenant-Colonel S. R. Christophers, Major H. E. Shortt and P. J. Barraud, has published a large number of papers during the year and has also contributed a number to the Kala-azar Memoir of the *Indian Journal of Medical Research* which was due to be published during the year. The memoir has not yet appeared, but with

the kind permission of the editor of that journal reference is here made to some of the most important points brought out by the papers appearing in this memoir.*

In the first place these workers were able to confirm the findings of Knowles, Napier and Smith, which were reported last year, on the development of the parasite of Indian kala-azar in the sandfly, *P. argentipes*. Seventeen wild flies fed on kala-azar cases were dissected and 5 were found to contain active herpetomonas-like flagellates; a number of wild flies which had not fed on patients were dissected but no other controls were carried out. In a second paper they reported the finding of flagellates in the gut of 14 flies out of 53 fed, most of the flies being laboratory-bred, and in a third paper on controls they reported negative findings in 116 flies fed on the blood of healthy persons at various periods of the year. In their second paper they stated that in no instance did they observe flagellates anterior to the proventricular fold but in a footnote, probably referring to observations at a later and more favourable period of the year, they stated that they had observed flagellates in the oesophagus. In yet another paper on these sandfly feeding experiments they observed that the female flies could be induced to feed a second time if they were segregated from the males immediately after emergence; out of 17 flies fed a second time, 4 were observed to contain flagellates. Summarising their observations up to the date of publication of this paper, they reported 222 dissections of flies fed on kala-azar cases with 52 positive findings. Finally, the Kala-azar Commission have been able to shew by cutting sections of the fed flies that on the fifth day the pharynx was infected in 6 out of 14 specimens, and that in the case of 2 flies which had taken a second blood-meal and were dissected on the seventh and eighth days respectively, there was a heavy infection of the buccal cavity.

The Kala-azar Commission reported negative findings in 22 flies fed on N.N.N. cultures of *L. donovani*, and also published a paper dealing with the technique they employed in breeding sandflies. After a re-examination of the slides of a flagellate found by Mackie in sandflies in Assam in 1914, Shortt concludes that the flagellate was a Bodo and not a *Herpetomonas*.

In a very careful study of the life history of the parasite of Indian kala-azar Christophers, Shortt and Barraud shewed that it went through a definite cycle of development; parasites of the same stage of development always appearing in cultures of the same age, the post-flagellate stage being reached about the eighth day. In other papers they shewed that the optimum temperature for development of the parasite in N.N.N. medium was about 28°C., that the range of development was from 16°C. to 34°C., and that the flagellate was fairly resistant to changes in osmotic pressure but did not withstand the action of water.

A number of animal infection experiments were carried out by the members of the Kala-azar Commission. Attempts were made to infect mice with flagellate cultures of *L. donovani* by feeding and by intraperitoneal inoculation. They failed to infect any mice by feeding them with culture material, but infected about 90 per cent. when cultures of more than 7 days of age were injected into the peritoneal cavity, although injection of younger cultures did not produce infection. It would thus appear that the parasite does not reach the infective stage until the seventh or eighth day. Attempts were made to infect monkeys directly or indirectly by means of bed-bugs fed

* This special memoir is now in press and will shortly be published. It contains some 30 papers describing all recent work upon the kala-azar transmission problem in India. Messrs. Thacker, Spink & Co., Calcutta, are the publishers. R. K.

on kala-azar patients with entirely negative results. Two other experiments on monkeys were reported, in which a systematic infection was produced by intradermal injection of infected spleen juice in one case and in another in which this material was introduced directly into the lumen of the gut.

P. J. Barraud of the Kala-azar Commission carried out a limited survey of the town of Madras during the month of July. He found *P. argentipes*, *P. minutus*, *P. squamipennis* and *P. papatasi*. The three first-named varieties have been previously recorded in Madras but not so the last-named. *P. argentipes* was discovered in practically every quarter of the town, but the largest numbers were observed in George Town which is the quarter most heavily infected with kala-azar. A more detailed survey was carried out in two streets; the kala-azar infected street was found to be heavily infested with *P. argentipes*, whilst in the other in which few, if any, cases of kala-azar had occurred there were very few *P. argentipes*.

An epidemiological study of the disease was made by Napier; all the aspects in the epidemiology of the disease, geographical distribution, seasonal incidence and so forth, were considered in relation to the various means by which the disease might possibly be transmitted. It was concluded that there was considerable evidence that the disease was not transmitted by direct means and that if it were transmitted by an insect there was considerable evidence in favour of the sandfly, *P. argentipes*. Two notes on the incidence of kala-azar on the Pusa Estate and in the surrounding districts were contributed by D. P. Michael; notes on kala-azar in the Ramnad district by T. S. Balasubramanian and on a new endemic focus at Kayalpatnam by Lieutenant-Colonel J. Cunningham and S. R. Pundit were contributed. The latter place is in the Madras Presidency about 50 miles from Cape Comorin; 56 cases were reported, mostly amongst Mohammedans. It is an interesting point that the Hindu community living alongside were practically unaffected. A report on a study of the environment associated with kala-azar incidence in Calcutta which was carried out in 1924 by Napier was published during the year. He noted that certain quarters in the city were practically free from the disease, whereas others were heavily infected. The importance of these observations was that they led to the undertaking of an entomological survey in Calcutta which in its turn led to the above-reported experiments with the sandfly, *P. argentipes*, being undertaken. The Kala-azar Commission and the Enquiry at the Calcutta School of Tropical Medicine investigated the *Culicoides* of Assam and Calcutta respectively; 4 varieties were reported by the former and 8 by the latter. The Kala-azar Commission reported that 193 specimens of *C. macrastoma*, the only variety observed to bite man, were fed on the peripheral blood of kala-azar cases but that on dissection on the third day none of these were found to contain flagellates.

Kala-azar Treatment. It is quite obvious that the pentavalent antimony compounds have come to stay and that the only excuse for adhering to the antimony tartrates is that they are many times cheaper than any of the pentavalent compounds at present available. Stibosan, the proprietary name adopted for von Heyden "471," has been obtainable throughout the year and has been extensively used in the treatment of kala-azar. Lieutenant-Colonel E. D. W. Greig and S. Kundu used the compound in the treatment of 14 cases and concluded that the mean sterilizing dose was a total of 2 grammes and the absolute sterilizing dose a total of 3.49 grammes; but in another very resistant case they reported that 5.6 grammes had failed to produce a cure. Napier, who has been using this compound for some time, contributed a short note on the question of dosage; he advocated the giving of injections three times weekly, giving an initial dose of 0.2 gramme and a maximum dose of 0.3 gramme for an adult and suggested that a total

dose of 3 grammes per 100 lbs. body weight was usually necessary to cure an ordinary case of kala-azar. K. N. Chatterjee contributed a paper on Stibosan in private practice, reporting good results after a very short course of injections. Lieutenant-Colonel Greig and S. Kundu treated 51 cases with urea stibamine and found the mean sterilizing dose to be 2.12 grammes and the absolute sterilizing dose (excluding one resistant case) to be 4.2 grammes. They reported a resistant case that had received 2 grammes of potassium antimony tartrate and 10.6 grammes of urea stibamine without being cured. Dr. U. N. Brahmachari collected reports of 27 cases of kala-azar cured with urea stibamine in from 32 hours to 7 days. He suggested an intensive course of treatment by giving a number of injections on the same day; he reported that he had done this without untoward symptoms. Major N. C. Kapur reported the results of treatment of 50 cases treated at the out-patient department of the Medical College. The series were controlled by blood cultures taken before and after treatment by Dr. Brahmachari himself. A remarkable point about this investigation was that the blood culture before treatment was in every case positive; an unusually consistent finding in view of the fact that many of the cases had already undergone treatment. All the cases recovered rapidly. In another paper Dr. Brahmachari and B. B. Maity reported a series of cases in which the diagnosis had been made by blood culture in 97 per cent. of cases and by spleen puncture in only 84.5 per cent. He also reported that the blood had become sterilized in 26 out of 37 cases within 12 days by the use of urea stibamine. S. Kundu reported a case in which he had administered urea stibamine intramuscularly without causing much pain, and another case in which an antimony rash had followed the administration of urea stibamine. Dr. Brahmachari published further details about the preparation of urea stibamine and also gave details of the preparation of two new pentavalent compounds. Stibamine glucoside, a compound prepared by the Wellcome Research Laboratories, was first used in the treatment of kala-azar by Napier; he reported the result of treatment with this compound in 10 cases. He found this compound far superior to sodium antimony tartrate and comparable to Stibosan and urea stibamine in its action. Cases were cured in less than one month. Subsequently, Greig and Kundu reported two cases which had been cured by this compound. Another new compound was also introduced by Napier as "Aminostiburea"; he reported very good results with this compound, which he considered compared very favourably with any of the pentavalent compounds so far used. B. Mozumdar reported on the treatment of 202 cases of kala-azar at the Campbell Hospital, Calcutta; most of these cases were treated with sodium antimony tartrate.

Greig and Kundu reported that as a general rule the blood-sugar in kala-azar was low. They however reported one case in which the blood-sugar was very high, 0.461 per cent.; this patient, aged 17, was passing as much as 38.4 grs. of sugar in an ounce of urine. Both conditions were apparently cured by urea stibamine and insulin.

Other forms of Leishmaniasis.—During the year Lieutenant-Colonel R. Row described a case of canine leishmaniasis that he had seen in Bombay. The parasites were found in ulcers on the ears, nose and lips of the dog, but there was apparently no general infection. Shortt and Brahmachari contributed a paper on the histopathology of dermal leishmanoid; the primitive cells of the cutis vera were heavily infiltrated, the epidermis was thin, but there was no sign of ulceration, and the cutis vera was markedly thickened.

MEDICAL HELMINTHOLOGY.

This branch of tropical medicine is such an important one that it may be best considered under three differen

headings:—(1) ankylostomiasis; (2) other helminthic infections; and (3) anthelmintics.

Ankylostomiasis. A detailed investigation has been made by Dr. A. C. Chandler of hookworm epidemiology on a tea estate at Moheema in Upper Assam. The infection rate was found to be 93.6 per cent., the average eggs per gram of faeces 1,070, and the index of infection ($\sqrt{\frac{\text{epg}}{100} \times \%^2}$) 317, or about three times that of rural Bengal. Soil pollution in the group studied was universal, definite defecation sites being habitually used; the sites selected were protected places usually about 50 to 75 yards from the habitations. There was also some scattered pollution in the tea itself, which probably accounts for the slightly higher rate of infection among the women than the men. Soil infestation with hookworm larvae was practically limited to the defecation sites, and it is quite evident that most of the infection occurs while standing on infested ground during defecation. Climatic conditions practically limit acquisition of infection to 7 months of the year, from mid-March to mid-October. A layer of thatch a few inches thick effectively prevents contact of feet with larvae, and when stools are passed in deep trenches or pits, surface infestation is almost entirely eliminated. If the coolies could be taught to defecate into the drainage ditches in the tea estate instead of on to the ground surface, infection in the tea would be practically done away with. *Ascaris* and *Trichuris* infections are present in 90 per cent. to 95 per cent. of the coolies, and were traced to the drinking of *hula* water, into which worm eggs are washed from stools deposited on the banks.

Mr. Senior-White has studied the influence of latrine installation on hookworm infection on Ceylon tea estates. These latrines are deep pits, with simple superstructure, dug in hard soil. When water seeps into them they become very serious mosquito breeding places. In the drier pits great numbers of fly larvae can be seen in the faecal masses but, apparently due to the absence of drier ground for pupation, no adults develop. Seven years after provision of latrines, thanks to constant vigilance, soil pollution is practically absent. Before the latrines were installed 98 per cent. to 99 per cent. of the coolies were found infected by the simple smear method of examination, whereas six years afterwards only 77 per cent. were found infected by Lane's D. C. F. method, and most of these were clearly very light infections, which would probably have been found negative by the simple smear method. After two further treatments the incidence was reduced to 69 per cent. and 46 per cent., residual infections being very light. Attention is called to the peculiar circumstance that as the hookworm infections were reduced by treatment with carbon tetrachloride, *Ascaris* infections increased.

Dr. V. T. Korke has made some observations on the life history and morphology of hookworms in nature, and has investigated the types of ground which are favourable and unfavourable for development of hookworm larvae; his experiments lead him to believe that unshaded ground covered by grass and vegetation is most favourable. In lieu of preventing ground pollution, which is often impracticable in India he thinks that something can be accomplished by urging the selection of defecation sites on ground found to be unsuitable for larval development. Even when development occurs the larvae frequently have a starved appearance; this was often observed in growths of long duration. Morphological distinctions between the larvae of *Necator* and *Ankylostoma* were found in the absence of a basal expansion of the buccal cavity in the rhabditiform larvae of the former, and also in the more anterior position of the genital primordium in infective *Necator* larvae.

Dr. Chandler has performed experiments in field and laboratory work which show that lateral migration of hookworm larvae does not occur, although larvae are easily distributed by a sprinkling of water. While

larvae climb vertically through coarse or sandy soil, impelled by a negative geotropism, migration on a soil wall, such as the side of a pit or ditch, is practically negligible. Experiments on the survival of healthy infective larvae on soils of different hydrogen ion concentration showed that their longevity on soil with pH 5.5 to 6 is as long or longer than that on neutral or slightly alkaline soil. A few larvae survived, during the hottest weather in Calcutta, for about three months. A comparison of different methods of discovering hookworm eggs and for measuring egg output made by Dr. Chandler shows Lane's D. C. F. method to be the best for diagnosis, and a modification of Stoll's method best for estimation of egg output. Using the D. C. F. method pushed to finality as a control, Stoll's method, with the modifications recommended, indicates the number of eggs per gram of faeces with remarkable accuracy. Dr. Chandler has pointed out that measurements of the degree of infection as well as of incidence are necessary to arrive at a fair estimate of the importance of hookworm in a community. He believes that a fairly accurate estimate of the degree of infection can be arrived at by ascertaining the average egg output per gram of faeces for the group, even though in individuals there is no close correlation between egg output and worms harboured, and the egg output varies considerably from day to day. To find a true index of infection it is necessary to take into consideration both incidence and degree of infection, and Chandler shows that a very fair relative index can be obtained by using the equation $\sqrt{\frac{\text{epg}}{100} \times \%^2} = \text{index}$, where epg represents

the eggs per gram of the infected individuals, and per cent. the incidence of infection. By this method the index of infection among coolies on an Assam tea estate works out at 317, whereas in jute mill coolies and rural inhabitants of Bengal it works out at a little over 100, or less than 100. In untreated groups in Porto Rico the index of infection is from 408 to 630.

Dr. Sweet in Ceylon has made observations on hookworm reinfections. Analysis of 8,239 egg counts showed that previously treated persons have a considerably lower infection intensity than untreated ones, especially in children. Reinfection was most rapid in the first three years after treatment, after which the intensity rates remained about the same up to the seventh year, and then began to rise. The percentages of persons found infected showed an initial sharp rise followed by a small steady increase. Dr. Sweet suggests 3 to 5 years as the probable average length of life of adult worms.

Other Helminthic Infections.—J. N. Maitra describes a very interesting case of an Indian male adult who died of jaundice. At post-mortem numerous ascarids were found and some of them had invaded the liver; two were imbedded in a necrotic area in the liver, one was in a bile passage, and three were in the gall bladder, which was firmly adherent to the duodenum. The contiguous walls of the duodenum and gall bladder had been perforated by ascarids as shown by the inflammatory adhesions.

Little further work has been done on filariasis. Dr. G. C. Ramsay has drawn attention to the scarcity of human infection in Assam in spite of the prevalence of *Culex fatigans*. Only two of 400 persons whose blood was examined at night were found infected, one of these being an Indian doctor with mild chyluria. Equine filariasis, on the other hand, is common in Cachar. The micro-filariae in horses are diurnal, and tabanids are suggested as probable vectors. *Dirofilaria immitis* is the commonest cause of sudden death among dogs in Assam.

N. Banerji recommends treatment of human filariasis by repeated doses of typhoid vaccine—20, 50, 100, 500 and 1,000 million every third day.

Dr. Chandler has studied the helminthic infections of Calcutta cats, and the extent to which cats might

serve as reservoirs for human helminths. Twelve species of parasitic worms were found, of which *Opisthorchis felinus* (61 per cent.), *Taniaformis* (42 per cent.), *Dipylidium caninum* (43 per cent.) *Belascaris mystax* (63 per cent.), and *Ankylostoma braziliense* (70 per cent.), were most common. Two new species, *Spirocerca felinus* and *Centrorhynchus erraticus*, and one new variety, *Strongyloides stercoralis felis*, were discovered, and an emended description of *Dipylidobothrium decipiens* was given. The occurrence of *Strongyloides* in 20 per cent. of the cats was of particular interest since *Strongyloides* had never before been recorded from cats in any part of the world. *Ankylostoma braziliense* was the only species of hookworm found in the cats, although in dogs it is commonly accompanied by *A. caninum*. *Gnathostoma spinigerum* was found to have a seasonal occurrence, adults having been found in over 31 per cent. of cats from August to November, and in none from November to February. Larvæ burrowing in the liver were found in 12 per cent. of the cats between January and March. Some interesting observations on the life history of this deadly parasite are the subject of a separate paper. Encysted larvæ are very common in snakes, but it is believed that the snake is an accidental host and becomes infected by swallowing the true intermediate host, probably an insect or mollusc.

The species of *Strongyloides* has been the subject of a study by Dr. Chandler. The described species fall into two distinct groups, a *S. papillosus* group parasitic in herbivorous animals, in which the tail of the parasitic form is bluntly rounded, and the eggs commonly hatch after leaving the host's body; and a *S. stercoralis* group parasitic in carnivorous and omnivorous animals, in which the tail is sharply pointed, and the eggs ordinarily hatch before leaving the host's body, or even before oviposition. A detailed description of *Strongyloides stercoralis felis* is given and comparisons made between this form and the *Strongyloides* of man and the *Strongyloides* of Asiatic monkeys and apes. The question of transfer of *Strongyloides* between cats and man is not settled; for the present the cat form is considered a hostal variety of the human species.

Dr. J. P. Cullen has recorded nine cases of infection with *Schistosoma japonicum* in Chinese in the Northern Shan States of Burma. Although all but one of these cases gave a definite history of residence in neighbouring parts of China, especially Yunnan, which has been shown to be an endemic locality, the very important question arises of the possibility of the infection establishing itself in Burma, if it has not already done so, and spreading over that country.

Dr. J. B. Christopherson has questioned Dr. Hamilton Fairley's suggestion, based on experiments on goats, that emetine may prove more effective than antimony tartrate in the treatment of human schistosomiasis. He collects the available evidence to show that antimony tartrate is lethal to the eggs imbedded in the tissues, as well as to the worms, and he is convinced that relapses after treatment are due to faulty therapeutic technique. Emetine is more toxic to the host, more expensive, and in Dr. Christopherson's experience less effective. Antimony tartrate has a very selective action on parasites and tissues and may be less toxic to *S. spindalis* than to human schistosomes. Dr. Christopherson does not believe that laboratory work can be substituted for clinical experience.

N. Prasad Shrivastava has reported a case of hydatid cyst of the right parotid and submaxillary glands. The patient recovered after it was opened and drained. The patient was a *Gond* who had presumably eaten vegetables contaminated with dog's faeces. Daughter cysts were encountered all over the field of operation. Dr. Frank Ware has reported one case of sterile hydatid cyst of the eye in India, and three cases of *Cysticercus cellulosus*, two of them ocular and one cerebral. Dr. Chandler has recorded a case of infection with *Bertiella satyri* in a Hindu child, the second case on record. What appears to be the same species has been

found in hoolock monkeys which died in the Calcutta Zoological Gardens. The worm was about 275 mm. in length, and about 10 mm. broad.

M. A. Moghe has described a number of new species of Cestoidea from Indian animals, and has discussed the relationships of the species and genera to which these worms are allied.

Anthelmintics.—Dr. Chandler and A. K. Mukerji have summarised the work done at the Calcutta School of Tropical Medicine on carbon tetrachloride and carbon tetrachloride accompanied by oil of chenopodium. They point out that an anthelmintic should be judged on the basis of (1) safety for the patient, (2) effectiveness in expelling worms, (3) simplicity of administration on a large scale, (4) lacking of unpleasantness in taking or in after effects, and (5) cheapness. No one anthelmintic can be expected to be effective for all kinds of worms. CCl_4 in doses of 3 to 5 c.c. is regarded as being as safe as any effective anthelmintic and distinctly safer than oil of chenopodium, providing (1) that the drug comes up to a certain standard of purity, (2) that it is accompanied or followed by a saline purge, (3) that it is not used in the case of under-nourished or very weak individuals or patients having hepatic cirrhosis or other liver lesions, and (4) that fats and alcohol, and preliminary starvation, are avoided when it is used, and a diet rich in carbohydrates is given. CCl_4 is well tolerated by young children, pregnant women and kala-azar and malaria patients. It is distinctly superior to chenopodium in eliminating Necators, but only on a par with it for ankylostomes. It is cheap and easily administered, the preferred method of administration being as an emulsion in skimmed milk. It has some action on *Ascaris* and *Oxyuris*, and promising results against the latter have been obtained from rectal injections of the drug emulsified in warm milk. There is practically no action against *Trichuris*, *Strongyloides*, or tapeworms. Accompanied by oil of chenopodium, its action against ankylostomes is superior to that of either drug alone, and the combined treatment is recommended for mixed infections or where *Ascaris* is common. The chenopodium is given in a capsule (15 min.) followed by CCl_4 in milk (60 min.). For field work it is suggested that these dosages might be reduced. The effect of the combined drugs on the host appears to be no greater than the same dosage of either drug alone. In experimenting on the effects of diet and other factors on the damage done by CCl_4 , Dr. Chandler and Major Chopra found that CCl_4 was very highly toxic for cats, in contrast to results obtained elsewhere, and the use of the drug in these animals appears to be absolutely contraindicated.

LEPROSY.

Dr. E. Muir, Leprosy Research Worker, Calcutta School of Tropical Medicine, reviews the year as follows:—

"Dealing with the Leprosy Problem in General.—During the year 1925 there has been a very remarkable increase in the interest taken in leprosy by the medical profession. This is due largely to the realization that leprosy, instead of being an infirmity and misfortune which cannot be remedied, is a highly remediable disease, especially when it is dealt with early.

Up till lately teaching with regard to leprosy in the medical schools and colleges of India has been next to nothing, and there are but few of the present generation of doctors who are accustomed to diagnose it from its early signs. Now that it has been realized that leprosy can be treated with success, efforts are being made by medical authorities to educate the medical profession and through them, the public at large, with regard to the essential facts of the disease.

The main effort has been made in connection with the British Empire Leprosy Relief Association and its Indian Branch. In January, His Excellency the Viceroy made an appeal for funds to place this newly started Association on a sound financial basis.

Up-to-date, over 17 lakhs have been gathered and a programme of work has been adopted by the executive of the Association which is as follows:—

(1) The appointment of a well-qualified medical man who shall carry on research work during part of his time and also visit various provinces where he shall deliver lectures to doctors and medical students, initiate clinics for the treatment of leprosy, especially of early cases, and otherwise give advice and stimulate local effort towards dealing with the disease.

(2) The special training of medical men in the diagnosis and treatment of leprosy. Doctors will be selected who are in charge of clinics in various central positions, such as large mofussil towns; epidemiological officers and those in charge of leper asylums will also be selected and sent, in the first instance, for training to the School of Tropical Medicine in Calcutta, to undergo a fortnight's course of special training in leprosy. Later on, it is hoped that, as more local experience is gained, this training may take place in connection with leper institutions in the various provinces.

(3) Propaganda work will be carried on extensively.

It is realised that what is required most in dealing with leprosy at the present time is to bring it to the light. There is no reason to believe that the disease is either increasing or diminishing at the present time. If, in spite of the ignorance of the disease which leads to the passing over of its early symptoms and not recognising it at the stage at which it may be most easily dealt with, leprosy in India is at present at a standstill, there is every reason to hope that, when the medical profession is as well informed with regard to leprosy as it is with regard to other common diseases, and when doctors have had an opportunity of educating the people at large with regard to this little understood malady, there will be a rapid diminution of its endemicity, if not a rapid stamping out of the disease from all but the most remote parts of the country.

Efforts being made in other countries.—In Australia leprosy has been a notifiable and quarantinable disease for three decades, and yet is still as prevalent as ever in some of the states. It is interesting to note that this is attributed to the early stages not being recognised or not reported by medical men; as in the case of a small outbreak among the natives of Roebourne, Western Australia, prompt isolation of the first four cases stamped out the disease. In Queensland unless cases found to be bacteriologically positive are isolated, it is not recognised that it is important that arrangements should be made at regular intervals to detect the early infective stage, while cases outside the lazarets should receive regular treatment.

In Canada there is a lazaret at Taracide to which lepers are admitted from all parts of Canada. There is another lazaret on Bentinck Island in British Columbia, in the former there are 10 and in the latter 9 patients. 'The importance of early diagnosis cannot be too much emphasised, because, if a leper is discovered within five years of his arrival in Canada, he can be sent back to his native country,' and because if early diagnosed he has a fair chance of recovery under treatment.

Other reports are given with regard to Morocco, the Soudan, the Central Pacific and many other parts of the world, showing that an increased interest is being taken in dealing with leprosy and in almost all cases emphasising the importance of recognising and dealing with it in its earlier stages.

Rat Leprosy.—Some interesting papers have been published by Professor Marchoux of the Pasteur Institute of Paris on rat leprosy. This disease is well known in the Parel Laboratory in Bombay where large numbers of rats are examined in connection with plague prophylaxis; and the study of this disease, the organism of which is different from that of human leprosy, though very similar to it, should furnish a useful and enlightening line of research. Whether rat

leprosy is to be found in human beings in India or not, it is difficult to say, as without careful examination, the signs appear similar to those of human leprosy; but the matter is well worth investigation. Apart from this, however, the study of the pathology of rat leprosy may shed much light upon human leprosy because of the great similarity between the two diseases.

Treatment.—Various investigators have recommended vaccines prepared either from leprosy nodules or from various types of acid-fast bacilli.

In the *Indian Medical Record* for July, Lieutenant-Colonel R. W. Row, of Bombay, recommends autolysed tubercle bacilli. 'The author is quite satisfied with the results in the small number of cases of leprosy in his care and treated by the autolysed vaccine, but, as they are far too few in number, he awaits the accumulation of a few more to be in a position to publish them. Suffice it to say that in nerve leprosy at any rate the cord-like thickened nerves have come to the normal after about thirty injections. The anæsthetic patches have disappeared in a few weeks, the atrophy has been controlled and the trophic ulcers made to heal rapidly.'

Lieutenant-Colonel F. J. Palmer, R.A.M.C. (retd.) reports good results in a few cases treated with copper salts.

With all these drugs, however, only small numbers of cases have been tried, and we think it is not sufficiently clearly understood that only prolonged trial on large numbers of patients with sufficient controls can constitute a fair test for any drug in leprosy.

Leprosy is a self-healing disease and almost any irritating substance, or anything capable of producing directly or indirectly 'protein shock,' may cause marked improvement at certain stages. Moreover the patient generally seeks medical advice when the sudden onset of the reactionary phase has produced marked swelling and erythema of old, hitherto little noticeable lesions and the unfortunate victim has suddenly become for the first time an obvious leper. But as these lesions will again fade of their own accord as the next phase comes on, whatever remedy is used will give the appearance of having produced a marvellous result.

In the Cullion Leper Colony in the Philippine Islands excellent therapeutic work continues, various combinations of chaulmoogra esters have been tried and the least painful on injection are found to be combinations with iodine and creosote. 'Nephritis gave three times as high a proportion among patients who have been treated than among those who were not treated, in spite of the fact that more early cases were included among the former; indicating that the prolonged use of ethyl ester chaulmoogrates damages the kidneys in some ways.'

In India we have been finding that the pure oil of *Hydnocarpus wightiana*, extracted from fresh, ripe seeds, causes, when injected subcutaneously, far less irritation than the esters, up to 25 c.c. having been given in some cases with practically no pain. It is likely, therefore, that injections of oil will take the place of injections of esters, especially as the former, as far as our experience has gone, is at least as effective therapeutically as the esters; it is moreover very much cheaper.

Too much emphasis has probably been laid upon the injection of drugs, useful as it is: even more important than injections is exercise in the effects it has in causing improvement. It is significant that in various provinces of Eastern India the word for 'leper' and the word for 'laziness' are synonymous. Leprosy may often lead to laziness, as the leper is often precluded from work, but it is equally true that laziness and lack of exercise produces the most ideal conditions for the growth of the lepra bacillus in the body. It is also equally important to eliminate from the body any concurrent or predisposing disease or other circumstances which may lower the general resistance of the body. This aspect of the treatment of leprosy has, up till now, been overlooked, but, as in tuberculosis,

the general treatment of the patient's condition must always take precedence of any special injections."

Colonel Palmer, R.A.M.C. (retd.) having decided to try the effect of various metallic salts in leprosy, commenced with the oral administration of copper sulphate in $\frac{1}{2}$ grain doses in pill form daily in courses of three weeks' treatment with one to two weeks' intervals. Two cases treated shewed in one instance enormous improvement, in the other apparent cure. But a very marked reaction was noted in the leprosy tissue. He next went on to the use of copper citrate intravenously; copper citrate $\frac{1}{2}$ grs., sodium citrate 4 grs. in solution; and of bismuth, given as tartrate intravenously in doses of 2 to 3 grains. The doses are given fortnightly over a period of two months or so. His results were as follows:—Slight cases, 5, which all shewed marked improvement or cure. Advanced cases, 3, all of whom shewed definite improvement. He concludes that the treatment is of such value that it may hold out a prospect of cure through the induction of specific reactions.

Major W. D. H. Stevenson writes of the Wassermann reaction in leprosy, using Hecht's modification. Of 15 anæsthetic cases, 2 gave a ++ reaction, 2 a — reaction, the rest a partial reaction. Of 37 tubercular and mixed cases, 7 gave a ++ reaction, 1 a — reaction, and the rest a partial reaction. The globulin content in leprosy blood as estimated by Noguchi's technique, is very high; certainly higher than that of treated syphilitic patients. Yet leprosy sera may have a high globulin content and only give a weakly positive or even negative Wassermann reaction. (As the subsequent and much more extensive work by Dr. Muir and Major Lloyd has shewn, a positive Wassermann reaction in leprosy appears to be always the result of syphilis, and not of leprosy; such patients improve, not only as regards their syphilis, but also with regard to their leprosy, on thorough anti-syphilitic treatment).

M. N. De records a case of nodular leprosy with extraordinary lesions closely simulating those of yaws. The lesions were quite atypical and very acute. Innumerable leprosy bacilli were found in films from the pustular lesions and the patient was clearly in an acutely infective state.

Dr. D. A. Turkhud writes to say that there is now some considerable evidence that *gangosa* exists in India as a disease quite separate from either leprosy or syphilis.

PULMONARY TUBERCULOSIS.

It can no longer be said that the medical profession in India is not awake to the ravages of this terrible disease in India. As paper after paper published all over the world of recent years has shewn, phthisis is an entirely different disease in the European and in the Asiatic. In the former infection usually occurs in infancy, or childhood, becomes latent, and may flare up in adult life; but phthisis is then a very slowly progressive disease with a relatively long period of years of life before the patient, and very considerable prospects of spontaneous cure. In the Asiatic—usually an immigrant to a big city from a rural district—the adult soil is virgin ground, and there has been no previous immunising infection in childhood; phthisis is usually from infection from the human and not bovine strain—owing to the habit of universal spitting—and it is a terrible and destructive disease, killing its victims in a period often to be measured within a few months.

No medical man working in any large Indian city can fail to be impressed with the awful phthisis problem. In Calcutta there are a few beds for patients on the roof of the Medical College Hospital, with a very extensive waiting list, and provision is made for European patients at the Presidency General Hospital. But there is not a sign of any real attempt to grapple with this terrible problem; and anyone who sees a considerable out-patient clientele during the year is bound to be saddened with the mournful procession of

dhobis, mistris, clerks and their relatives stricken with a rapidly fatal disease, and with no prospect of proper nursing and care. If there is any philanthropist in Bengal who wishes to deserve well of the city of Calcutta in which he has made his fortune, the writer would impress upon him the terrible position with regard to phthisis in the Indian cities. Dr. Crake, Health Officer to the Calcutta Corporation, has drawn attention to this matter in report after report; Dr. Sandilands, Health Officer, Bombay, has also commented upon it; and small tuberculosis dispensaries attempt the impossible task of grappling with this problem in the two greatest cities of India. But the real position is far beyond their strenuous but inadequate endeavours. India possesses unrivalled hill stations where strong sunlight and the purest of mountain air—equal to any in Switzerland—are to be found; it is there that healing sanatoria can be founded. They are not merely badly, but most desperately needed.

This journal may perhaps have contributed slightly to focussing attention upon this terrible problem; but we are glad to note that the *Calcutta Medical Journal* and the *Indian Medical Record*, with its special tuberculosis number last July, have also taken it up. Phthisis is not a subject to argue about in Indian cities; it is a veritable messenger of death itself.

Of very numerous papers dealing with this problem in India, we would select first that by Sir Leonard Rogers on the incidence of pulmonary tuberculosis in India in relationship to climatic factors. India is a land in which the relationship of rainfall to phthisis incidence can be especially well studied, since its rainfall incidence varies from 500 inches a year at Cherrapunji to 5 inches a year or less in the N. W. F. Province. And all over the country there are carefully collected jail and army statistics for investigation, whilst accurate meteorological data have been maintained for several decades. The following rates shew the very close co-ordination between phthisis incidence and rainfall:—

	Phthisis ; incidence per mille.	Rainfall ; inches per annum.
Bengal and Orissa ..	13.7	75".
Madras Presidency ..	10 to 12 in different parts.	30 to 50".
West Coast ..	10.9	100".
N. W. Frontier ..	4.3	5" or less.
Himalayan hill tracts	3.6	

There exists a well-defined belt of territory, with a phthisis incidence well below the average, and about 5 to 7 per mille, which extends right across Central India, and includes Sind, E. Rajputana, Central India and the Central Provinces. This belt has a low or moderately low rainfall, limited to the period of the south-west monsoon. The Deccan has the lowest absolute humidity in India during the monsoon period at a figure of 2.7, also a specially low phthisis incidence. These areas correspond to those with a very low incidence of phthisis. On the other hand the very high incidence in Bengal and the west coast closely corresponds to the heavy rainfall from the S. W. monsoon; that in Madras Presidency to the N. E. monsoon; and the moderately high incidence in Burma to the fact that the Burma coast feels the full effect of the monsoon currents. In Central India a low phthisis incidence is associated with but feeble monsoon currents of low penetration.

Assam shews exceptional figures, a low phthisis rate of 4.5 per mille with a high rainfall. Here, however, the Surma valley is protected from heavy rainfall by the Arrakan and Tippera hills; and the Brahmaputra valley by the Khasi and Jaintia hills. The author concludes as follows:—"The direction, steadiness and strength of the rain-bearing winds appear to be the most important factors, in addition to high rainfall and absolute humidity, in influencing the prevalence of

pulmonary tuberculosis in India. . . . Their bearing upon the choice of residence for an actual or potential phthisis patient and on the choice of sites for sanatoriums is obvious."

In other papers which are very numerous comment is made upon the aetiological factors in phthisis in India. Of these we would especially select that by Ashutosh Roy, as a paper which is the result of many fruitful years of work in India by an author very fully acquainted with the conditions which he describes. The factors which he especially incriminates in the great incidence of phthisis in Indian cities are the following:—the substitution of city for rural life; the multiplication of industrial concerns and institutions throughout India; the increase in means of communication; universal spitting; the increase of slums and *bustees*; the dust, heat, and humidity of most Indian climates; the debilitating influence of concomitant malaria and other tropical fevers and diseases; the joint family system among Hindus; leading to the existence in most households of retainers who are poverty-stricken and who constitute foci of the disease; early marriage and the purdah system; the cramped conditions of school and college life in general in India; insanitary restaurants, public places of amusement and public conveyances throughout the towns and cities of India; alcohol; and, with regard to Hindus, the general insufficiency in proteins of the Hindu diets. It is a long but interesting list; but it is difficult to see how it can be dealt with. The solution of the phthisis problem in India is similar to that elsewhere; proper town-planning and the eradication of slums; yet under present Indian financial conditions such a solution appears as distant as the Greek calends, although the work of the Calcutta and Bombay Improvement Trusts constitutes a notable step in advance.

Rai Bahadur G. C. Chatterji comments on the considerable number of Indian patients who have at one time or another of their lives had declared tuberculosis and yet have lived to a more or less healthy adult age or even later. Lieutenant-Colonel R. Row's autolysed tubercle vaccine has already been referred to in the previous section on leprosy, and also in our review for the last year. It is prepared as follows:—a 4 to 6 weeks' growth of tubercle bacilli upon glycerinated brain-agar is killed and autolysed for some months. A putty-like mass of agglutinated tubercle bacilli results, many of which are now non-acid-fast. This is de-fatted, dried, weighed and the requisite doses made up in saline. Doses of from 0.01 to 0.02 mgm. are recommended for weekly injections. In guinea-pigs the results are conflicting; but these animals are unsuitable for experiment, as it is impossible to control the degree and intensity of tubercular infection in them. Indian patients further are difficult to deal with; many of them are half-starved, phthisis is usually an acute disease in the Indian but little amenable to any form of treatment, whilst their social hygiene is bad. But the results in general are perhaps encouraging.

RELAPSING FEVERS.

The remarkable work by Lieutenant-Colonel J. Cunningham on the serology of the spirochæte of relapsing fever was the subject of a paper read before the Royal Society of Tropical Medicine and Hygiene, and has been fully reviewed in our issue for January, 1926, p. 30. Briefly, he has shewn that the spirochætes present in the first febrile attack and those present in the first febrile relapse shew entirely different agglutination reactions, although morphologically identical. Inasmuch as such serological reactions are usually held to be the most constant and determinative features of closely allied bacterial strains, this opens up a wide field for investigation. If these two different types be designated *A* and *B* respectively, then the first febrile attack may be due to the *A* strain, but more rarely to the *B* strain; and strains *A* and *B* alternate

regularly. The work was carried out on monkeys at first, but later on Madras squirrels, which proved suitable experimental animals. The use of a spirochætal vaccine was also studied. This work is still in progress; but already it raises most important questions as to the mutation of bacterial types, the relationship of the true cholera vibrio to its morphological allies, e.g., and the like. In the discussion which followed Colonel Cunningham's paper some of the most distinguished bacteriologists in London took part; and the further and fuller report promised later will be widely studied with much interest.

T. K. K. Nair draws attention to the frequency of acute dysentery just before or just after the first febrile crisis in relapsing fever patients. He has failed to find *entamoebæ* in such stools, although the relapsing fever spirochæte is, of course, present, as blood is present in the dejecta. Many deaths occur from this cause in patients already weakened from the first attack of fever. Emetine in treatment of this dysentery proved a complete failure.

The spirochæte of rat-bite fever has been the subject of an unfortunate controversy during the year. To Lieutenant-Colonel R. Row belongs the credit of first clearly demonstrating the existence of this spirochæte and of this disease in India (Bombay) many years ago; although—as Robertson points out—probably Vandyke Carter saw it as long ago as 1887. To Dr. M. J. Parmanand belongs the credit of proving that it shews the presence of terminal flagella—(difficult to stain and to make out, as admitted by every one who has worked on the disease, but undoubtedly there);—that it thus corresponds in morphology with the strains isolated by the Japanese and English workers; and that the common bandicoot, *N. bengalensis*, is its commonest host in Bombay. The figures for incidence were for *N. bengalensis* in 11 per cent.; *Mus rattus* 2 per cent.; *M. decumanus* nil. Dr. Parmanand's inoculated animals were sent to Professor Futaki in Japan, who also exchanged the Japanese strain with the Bombay one; and the identity of the two species was confirmed by both workers. Colonel Row still claims that the Bombay strain, first isolated and examined by himself, differs from the Japanese one; but the writer, at least, has seen the terminal flagella and is prepared to support Dr. Parmanand. In Calcutta the disease is now almost a common one. The patients were admitted during 1925 to the Tropical Diseases Hospital for Tropical Diseases, from each of whom *Spirillum minus*, the causative agent of rat-bite fever, was isolated in inoculated animals; whilst other cases were seen in out-patients, one of whom proved curiously resistant to courses of injection with organic arsenical compounds.

The recent epidemic in Madras of relapsing fever appears to have disappeared, to judge from recent reports.

DIABETES.

Major R. N. Chopra and Dr. J. P. Bose record complete failure in the treatment of diabetes with *telakuchia* (*Cephalandra indica*), an indigenous drug with a certain reputation in the treatment of diabetes by the indigenous systems of medicine in India. On examination the extract is shewn to contain an enzyme with amylolytic properties, a hormone, and traces of an alkaloid. None of these produced any fall of blood-sugar when injected into rabbits. The fresh juice was tried clinically on 6 patients with diabetes without in any way affecting their blood-sugar or urinary sugar content.

S. L. Bhatia and G. Coelho record the results of a series of observations on the blood-sugar of Indians; 38 normal Indians who lived in Bombay being examined. Of these 18 lived on a mixed diet, whilst 20 were pure vegetarians. The vegetarians shewed an average blood-sugar content of 0.149 per cent. as against a figure of 0.116 per cent. for the non-vegetarians; they also shewed less carbohydrate tolerance, and glycosuria was more common amongst them. The first author

has also continued these studies further. The average blood-sugar content for persons in Europe is given by different authors as being about 0.1 per cent. as against the above figures, whilst the sugar tolerance (after the ingestion of 50 grs. of glucose) is normal. Of 20 vegetarian Indians examined, 12 shewed a trace of sugar in the urine after ingestion of this amount of glucose, whilst their average blood-sugar when in health was 0.149 per cent. Persistent ingestion of a diet rich in carbohydrates appears to lower the renal threshold for sugar in vegetarians in India.

Rai Bahadur Dr. U. N. Brahmachari and P. B. Sen also contribute to the same problem from Calcutta. They conclude that defective sugar tolerance is manifested by many medical students in Bengal living on a diet rich in carbohydrates, and that such subjects are potential diabetics.

L. M. Ghosal comments on the frequent apparent failure of insulin treatment in India. He notes that (a) patients with marked diabetes may still shew no pancreatic defect, when tested by Cammidge's method. Some of these live for a long period of years in good health. (b) Another group may shew very marked pancreatic defect, and have no glycosuria. (c) A third group shew typical glycosuria plus pancreatic defect; these are always in bad health, shew rapid emaciation, and respond well to insulin. The use of insulin should be confined to the third group. His statements are controverted by Dr. J. P. Bose, who states on a basis of some 400 patients treated that insulin treatment is not ineffective in Bengal. Cammidge's chemical test on the stool for pancreatic deficiency is not reliable, and the Mayo clinic considers it "both valueless and misleading." It measures only the excretory activity of the pancreas; not its endocrine activity. The author mentions nowhere in his article the glucose tolerance test, which is the test for activity or otherwise of the islet cells of Langerhans. Insulin treatment is of the greatest possible value in Indian practice, if patients be properly selected and controlled.

"DEFICIENCY DISEASES": EPIDEMIC DROPSY; LATHYRISM, ETC.

In a final paper Majors Acton and Chopra summarise their work with regard to *epidemic dropsy*. The conclusions of these authors—based upon exhaustive experimental study—are as follows:—

Epidemic dropsy and epidemic beriberi are different clinical aspects of a toxic syndrome caused by the ingestion of certain poisonous pressor bases formed in husked, parboiled and stored rice under certain conditions of temperature and humidity. Such diseased rice can easily be detected by the water test, when the diseased grains shew a dense white opacity in more or less of their substance, as compared with the normal translucence of healthy rice. In such diseased grains a spore-forming bacillus of the *B. vulgatus* group is constantly found. These bacteria attack the rice, particularly during the hot, humid months of the monsoon, and especially when the grain is stored in unventilated rooms and godowns. In highly polished rice, with the aleurone layer removed, such rice is especially liable to invasion by these bacteria. Further, parboiling kills the enzymes in the grain and renders it still further liable to bacillary invasion. These invading bacteria have been demonstrated, together with their spores, not merely upon the surface, but in sections within the diseased tissues of rice which has caused the two diseases concerned.

Experimentally, rice sprayed with emulsions of culture of this bacillus, under the necessary conditions of temperature and humidity, forms exactly the same poisonous pressor bases. Under other conditions of temperature and humidity infection of the grain does not occur.

These poisonous pressor bases have been extracted (a) from diseased rice which has been the cause of the diseases in man; and (b) from rice experimentally infected under the above conditions in the laboratory.

When tested under the conditions of rigid pharmacological experiment they produce the symptoms characteristic of epidemic dropsy; oedema, heart effects, increased intra-ocular pressure, para-sympathetic paralysis; controls with extracts from normal and non-infected rice do not produce these symptoms. In sterile rice medium inoculated with this bacillus the same pressor bases are formed and on experimental test have the same actions. The neurotoxin which seems to be responsible for beriberi is only produced at a storage temperature of 50°C., and under anaerobic conditions. The epidemic dropsy toxin, on the other hand, is water-soluble, whereas the beriberi toxin is alcohol-soluble, and the former is more readily produced. The water-solubility of the epidemic dropsy toxins leads to their presence in the cooked rice taken by Hindu widows, and hence to their special susceptibility to epidemic dropsy, inasmuch as they take a sole rice diet of wet-cooked rice. Finally, individual susceptibility, which largely depends upon the "barrage" presented by the liver to all pressor bases, which it is largely capable of adsorbing and neutralising, and of the endocrine and especially of the adrenal mechanism, controls the incidence of the disease, determining which—of many exposed—to infection will develop the disease. The pericarp of the rice contains the "vitamines" and these occur in association with a layer of protective bacteria in the pericarp, which not only defends the rice from invasion by the poisonous bacteria mechanically, but also defends it by bacterial enzyme action; thus explaining the rôle of the vitamins in antagonism to beriberi and epidemic dropsy. Lastly, adrenalin, administered both subcutaneously and by the mouth has proved the most efficient line of treatment for cases of epidemic dropsy.

In connection with *lathyrism* the position is obscure. As is well known, Major Acton attributes this disease to the ingestion of *khesari dal* which produces certain poisonous principles under certain conditions of temperature, humidity and harvesting; also he has the advantage of having extensively studied the disease upon the spot in the districts where it occurs. Major L. A. P. Anderson, A. Howard, and J. L. Simonsen have continued their studies upon lathyrism in 1925. *Khesari* seeds, of *Lathyrus sativus*, contain no alkaloid. Feeding experiments with these seeds in ducks and monkeys over long periods did not produce any of the symptoms of lathyrism. In the fields, however, *khesari* is usually contaminated with a weed, *akta* (*Pisum sativum* var. *angustifolia*), and this contains the alkaloids vicin and divicine and a glucoside, viciamin. On inoculation into guinea-pigs divicine produces characteristic symptoms and death. *Akta* feeding causes death in ducks, together with a very characteristic train of symptoms affecting the nervous and muscular symptoms, as also especially well shewn in experimental monkey. Some of these symptoms correspond to those of lathyrism in man, but others do not; and the authors conclude that they cannot yet state that *akta* weed is the cause of lathyrism in man.

Of biochemical studies in connection with deficiency diseases in general, the studies in blood chemistry of normal Bengali students by H. N. Mukherjee and J. C. Saha deserve notice. These workers studied 40 normal Bengali students. They find that the non-protein nitrogen, total nitrogen, urea and creatinin content of the blood in these subjects was less than normal; on the other hand the uric acid content was definitely higher. In a subsequent study the first author continues the same work. The calcium and inorganic phosphorus content do not differ from generally accepted normal standards; but the cholesterol content was considerably lower than in Europeans; 124 to 160 mgms. as against 140 to 170 mgms. The Bengali diet may perhaps be deficient in cholesterol.

DISEASES OF THE THYROID.

Closely connected with such biochemical studies comes the study of diseases associated with the thyroid gland.

And here the first place must be accorded to a long and interesting paper read before the Ulster branch of the British Medical Association by Lieutenant-Colonel R. McCarrison upon this subject, which—over many years of careful experimental work—he has made particularly his own.

Thyroxin, he states, is the most important product of the thyroid gland. In general the thyroid is the regulator of the rate of metabolism in the body; also the gland is essential to iodine metabolism in the body. Kendall has further extracted from the thyroid an active principle which is mainly concerned with the nutrition of the skin and its appendages.

Thyroid disorder may begin (a) at the threshold of absorption in the intestine. (b) Secondly, there may be interference with the normal functions of the gland in disturbance of the utilization of its products in the tissues. (c) The medium of communication between the threshold of absorption and the threshold of utilization is the blood plasma, which may also be disordered.

Turning to disorders at the threshold of absorption, there may be inadequate absorption of iodine or of tryptophane. The aetiology of simple goitre is not as simple as supposed, but deficient iodine intake is a most important factor, and the addition of iodine to water supplies in many endemic goitrous areas is now a common practice. But at Christchurch, New Zealand, although addition of iodine to the diet lowered the goitre incidence in children in the schools from 55 to 39 per cent., yet the 39 per cent. incidence in previously non-goitrous children shews that simple administration of iodine is not the complete solution of the problem.

Secondly, filthy surroundings in animals lead to the production of goitre in them. The iodine intake may be sufficient, but the iodine absorption from the gut may be interfered with by bacterial action. Certain bacteria can remove iodine from organic media containing it *in vitro*, and hence probably *in vivo*. Continued ingestion of such bacteria in polluted water-supplies might cause goitre.

Thirdly, want of balance in the diet may cause thyroid hyperplasia, or excess of certain proteins or fats. Cod-liver oil is of importance in providing both iodine and vitamins.

Fourthly, excessive ingestion of lime salts for prolonged periods may cause colloid goitre.

In general, goitres arising in consequence of abnormal conditions at the threshold of absorption are preventable by the additional provision of iodine, provided that the iodine is adequately absorbed; i.e., when given with a well-balanced diet and to a healthy gut.

Turning to disturbances at the threshold of utilization of the thyroid products, after thyroidectomy in animals, as a rule, nothing is noticed for 18 days. In young lambs or kids growth then stops, whilst in adult animals there is failure of skin nutrition or of intelligence. The function of the gland appears to vary with the species of animal concerned and with its age. After incomplete thyroidectomy there is again an 18 day latent interval, and then compensatory hypertrophy of the thyroid remnant. Disturbances at the threshold of utilization are not always amenable to control by iodine administration, as the thyroid hyperplasia is the result of biochemical changes in the cells and tissue plasma. Iodine is—as it were—the lubricant of the thyroid engine, not its fuel.

Turning to clinical types of goitre, adeno-parenchymatous goitre has its favourite haunts in the great mountain ranges of the world; the incidence of the disease is low in childhood, but gradually increases with advancing age. It is associated with grossly insanitary conditions of life, and especially with contaminated water-supplies. It is curable by such drugs as thymol, and it can be prevented by providing pure and protected water-supplies. The administration of iodine to adults suffering from this condition is likely to lead to hyper-thyroidism.

Diffuse colloid goitre would seem to be most often found in low-land localities. It does not seem to shew the same association with cretinism that the true adeno-parenchymatous goitre does. The nearest approach to the experimental production of colloid goitre is obtained by feeding animals on food containing excess of lime, when colloid storage occurs almost to the exclusion of active secretions. In animals this condition can be prevented by the addition of iodine to the food containing excess of lime. According to Levin diffuse colloid goitre has its highest incidence in early life and tends to disappear after full maturity has been obtained.

With regard to childhood goitre, many such swellings are physiological rather than pathological, and a minority only of such swellings should be classified as true goitres. In the Himalayas the chief incidence is in boys of 9 years of age, and in girls of 10. Childhood goitres shew a marked tendency to spontaneous disappearance.

In certain parts of Switzerland 70 to 100 per cent. of the children are goitrous, yet only some 3 to 9 per cent. of young men are rejected for military service on account of goitre.

In general, concludes the author, in all metabolic diseases, including goitre, a multiplicity of factors is present, rather than a single one. The time has come when we must search more closely for the causes of thyroid gland disorders at the threshold of absorption in the intestine, in disorders at the threshold of utilization in the tissues, and in disturbances in the cell and tissue plasma of the gland itself.

Lieutenant E. A. Davies, I.M.D., and Assistant Surgeon P. Bell, I.M.D., advocate the intravenous use of sodium iodide in goitre, a solution of 1 grain per 1 c.c., and doses of 5 to 6 grains given intravenously every third to fourth day. In nine cases seen in the Chin Hills, marked benefit occurred in all, but the authors are doubtful of the permanency of the results.

The question of deficiency and dietetic diseases in India cannot be passed over without drawing attention to the comprehensive paper by Majors Acton and Chopra to the Medical Section of the Asiatic Society of Bengal on "Indian Diets in Relationship to Health and Disease," read on the 15th April, and summarised in our issue for July, 1925, on p. 341.

PNEUMONIA, BRONCHITIS AND ASTHMA.

During the year considerable attention has been called to the importance of pneumonia in the general death-rate in India. Thus, on an analysis of the causes of death in 1,600 consecutive post-mortems in Calcutta, Sir Leonard Rogers found pneumonia and allied diseases to be the cause of death in 27 per cent., as against a corresponding figure of 17 per cent. in 1,000 post-mortems held in London. At the annual meeting of the Assam branch of the British Medical Association, Dr. G. C. Ramsay drew attention to the considerable mortality among tea coolies in Assam from pneumonia, and incriminated as possible factors their habit of sleeping on the floor of their huts during the cold weather, and the heavy incidence of *Ascaris* infections which might possibly cause lung irritation. He asked whether the Pasteur Institute at Shillong could not investigate the problem in Assam, type the local strains of pneumococci, and issue a prophylactic vaccine.

Of greatest interest among the papers dealing with pneumonia during the year is Sir Leonard Rogers' important study of the relationship of pneumonia incidence with climatic factors in India. Taking the figures for jails, which are accurate and reliable, the following is the average incidence of pneumonia per mille of population:—Indus valley, South, including Sindh, 50; North Indus valley 25.8; Gujerat 25.5; all India 13.3; and at the other extreme of the scale the Burma coast 4.2, and South-East Madras 5.8. Baluchistan shews the highest pneumonia rate in the whole of the Indian army. As to seasonal incidence, 45 per

cent. of the pneumonia occurs during the cold weather, 31 per cent. during the hot weather, and 24 per cent. during the rains. There is a very close correlation between a high pneumonia rate with scanty rainfall and low absolute humidity. A low minimum cold-weather temperature favours the prevalence of pneumonia, and vice versa. Further, pneumonia is most marked in and shews the closest relationship with areas where there occur the greatest diurnal variations of temperature during the cold weather. In the North-Western Frontier Province, with such a diurnal variation of 30°F. and upwards, the incidence of pneumonia is very high. In the very low pneumonia areas of South-East Madras and Lower Burma the diurnal variation is the smallest shewn in India. The cold northerly winds that prevail over Northern India during the cold weather, favour a high pneumonia incidence. Chills produced by the conditions thus summarised are the most important exciting cause of the frequency of pneumonia in North-Western India.

Lieutenant-Colonel J. Cunningham, Major J. A. Cruickshank and S. Ramakrishnan have determined the types of pneumococci present in cases of pneumonia in South India, and give the following figures: type 1 = 62 per cent.; type 2 = 10.7 per cent.; type 3 = 7.2 per cent.; type 4 = 21.4 per cent. Captain R. H. Malone records a large scale experiment on the value or otherwise of prophylactic inoculation of Indian troops in Baluchistan with a vaccine prepared from types 1 and 2 strains; made up to a total strength of 1 c.c. = 5,000 millions; and two doses, each of one c.c. being given at intervals. Among 2,996 men inoculated the pneumonia incidence was 9.3 per mille; among 5,227 non-inoculated controls it was 10.7 per mille. The difference is inconsiderable. His statistics are studied by Major H. H. King who agrees that the use of the vaccine did not diminish either the pneumonia incidence or morbidity.

Nand Lal advocates a selective culture medium for the pneumococcus and gonococcus. Trypsin blood agar and potato blood agar were found to be better than simple blood agar; the former is especially suitable for the gonococcus, the latter for the pneumococcus. Age reduces the value of the medium from the point of view of yield for vaccine preparation.

Captain A. K. Nandi records an obscure case of pneumococcus infection in which the patient, a sepoy, was admitted with severe dyspnoea and precordial pain, but no pleural pain. A pleural effusion followed, and hæmoptysis at a late stage; finally 32 ozs. of fluid were withdrawn and shewed abundant pneumococci; the case appeared to have been one of central pneumonia with aberrant symptoms.

Turning to *asthma*, Major R. N. Chopra and Dr. Sudhamoy Ghosh discuss the pharmacology and therapeutics of *basak*—(*Adhatoda vasica*) an evergreen herbaceous shrub which grows abundantly all over India, and which has a local reputation. Its active principles are an alkaloid, vasicine, and an essential oil. Vasicine causes slight but persistent bronchodilatation in experimental animals, a slight fall of blood pressure and slight slowing of the cardiac rhythm. The fluid extract has well marked expectorant properties, tends to liquefy the sputum, and relieve bronchial spasm, and is of value in asthma, although of no value in pulmonary tuberculosis.

Majors Acton and Chopra contribute an important article on the treatment of asthma. Asthma is not a disease, but a symptom-complex caused by various bases, some, volatile, others non-volatile, and all probably of protein origin. In their opinion individual susceptibility to these bases is largely a question of adrenal and thyroid function; animals with high endocrine function resist the action of these bases; whilst animals with low endocrine function may be divided into those with low sympathetic endocrine function, and those with low parasympathetic function. In the group of patients with sympathetic predominance come patients who are susceptible to volatile emanations from horses,

cats and other animals; those attacked with asthma after certain articles of diet; here the treatment is to apply dermal sensitiveness tests, determine to which emanation or food the patient is sensitive and eliminate the cause; to raise the endocrine functions by adrenalin and thyroid administration, improve the metabolism by soamin, and treat any intestinal infections, such as with *E. histolytica*. In this group the eosinophile count is always high.

In the group of patients with vagal predominance, irritation in the area supplied by the vagus nerve is of importance; nervous asthmas, asthmas due to nasal defect or irritation, bronchitis with developed sensitiveness to the various causative micro-organisms fall into this group. Here the treatment is to remove all sources of irritation, increase the general resistance, administer autogenous vaccines, and advise fresh air and a liberal diet. Finally stasis of decomposition products in the blood, such as carbon dioxide in cardiac asthma or in renal asthma, may be a causative factor. Here cardiac tonics, etc., are indicated, and drugs acting on the central nervous system, such as morphia, will only give temporary relief.

The treatment of asthma, in brief, depends upon a careful and thorough examination of the patient, in order to ascertain its causative mechanism before appropriate treatment can be prescribed.

In connection with *bronchitis* S. V. Mathur and K. N. Zutshi record eight cases with *Monilia* and *spirochaetes* constantly present in the sputum, most of them sub-acute or chronic, but with acute febrile exacerbations and in some instances hæmoptysis; autogenous vaccines made from the *Monilia* proved useful.

TYPHUS AND TICK-TYPHUS.

Captain G. R. McRobert claims that the ordinary text-book statement that (louse-borne) typhus can only be nursed and treated on an expectant policy is nonsense, basing his claim upon an experience of the treatment of some 300 cases seen in Mesopotamia. We know that the period of the disease is self-limited, hence active therapeutic measures are not merely indicated, but are very necessary. Digitalis, strychnine and pituitrin should be pushed from the commencement of the disease, and brandy given if there is no cerebral irritation. Lumbar puncture with a fine needle is of value for the severe headache; intravenous sodium citrate for threatened thrombosis. One of the most important indications is to secure sleep at all costs during the early nights of the attack, in order to conserve the patient's strength, cold sponging, morphia and atropine being advocated; every typhus patient must have sleep for the first 6 or 7 days of the attack every night, even though resort be had to opium or morphia. Saline therapy is of value in the later phases of the disease, both rectal and intravenous. "Imperial drink" should be given in large quantities. Bed sores are a difficult problem, best dealt with by air pillows and water beds. As post-sequelæ defective memory, deafness, and deficient emotional control are noteworthy. The patient, if a European, should be sent on long furlough to Europe.

Lieutenant-Colonel J. W. D. Megaw, Major F. B. Shettle, and D. N. Roy discuss the occurrence of nine cases of "tick-typhus" which occurred among British troops on manœuvres in the Saugor-Jhansi area. The Weil-Felix reaction was positive to a titre of 1 in 80 in two of the cases, but completely negative in five. The disease is much milder than louse-borne typhus. Conjunctivitis and sore throat were marked symptoms. The temperature charts shew marked remissions—almost intermissions in some cases. The paper is illustrated by colour plates shewing the rash and with many photographs, and the movements of the individuals prior to the manifestation of symptoms are discussed. There is no clear evidence of tick-bite in any of the cases, but ticks abounded in the jungle-covered country in which the camps were situated.

Dr. C. E. S. Norman and C. S. Ramchandran record a still further case, that of a retired Indian army Colonel living at Trichinopoly, but a recent immigrant from elsewhere. The fever was of sudden onset with slight shivering, was continuous for 19 days; and ended by lysis. A discrete rash appeared on the third day; there was marked ocular congestion, severe headache and abdominal pain. There was no definite history of tick-bite, but his previous bungalow had been infested with ticks.

In summarising the position with regard to this malady, Colonel Megaw gives the following description of tick-typhus:—There is usually the history of a tick-bite or the patient has been in a jungle or in a house infested with ticks. After an incubation period of from one to three weeks, fever sets in with headache, joint pains, and often shivering. Sore throat and conjunctival congestion are features of some cases. The rash appears about the third to the fifth day, is a rosy, macular eruption, rather profuse and extending all over the body; later becoming dark-red and sometimes petechial. The fever lasts for 12 to 20 days and ends by lysis, more rarely by crisis. The Weil-Felix reaction as a rule is negative, and blood cultures give negative results. After convalescence, the cutaneous staining from the rash persists for some weeks. To this clinical entity he proposes that the name "tick-typhus" shall be provisionally applied. The disease closely resembles the Rocky Mountain spotted fever.

SNAKE-BITE.

A curious feature of the year is the number of cases of snake-bite of which details are given in the literature. Colonel F. Wall (ret'd.) describes the case of a sepoy, bitten at Karachi at 5 A.M. when on the way to the latrine by an *Echis carinatus* and admitted to hospital at 8 A.M. The site of the bite was incised, permanganate crystals rubbed in and 40 c.c. of antivenene given intravenously. By 2-30 P.M. the patient was restless, and had bleeding from the gums, hæmoptysis and copious oozing of blood from the wound. Pituitrin and hæmostatic serum were given and calcium lactate, 10½ grains subcutaneously in solution in 72 hours. The patient died from hæmorrhage 87 hours after being bitten. Once *Echis* venom has decalcified the blood, asks Colonel Wall, is it of any use to inject calcium salts? Also study is wanted of the best methods of calcium administration after viper bite.

S. A. S. Chuhar Singh, I.M.D., describes another case of *Echis* bite in a woman 5 months' pregnant at Hurnai in Baluchistan. Severe local pain and swelling ensued, and the patient commenced to bleed from everywhere. She gave birth to a still-born foetus 76 hours after having been bitten, and died herself 16 hours later. Jemadar S. A. S. C. Singh, I.M.D., records a further fatal case of a Mahomedan woman aged 30, bitten on the left ankle by an *Echis*. Local incision, rubbing in of permanganate crystals and large doses of calcium salts, both subcutaneously and orally, constituted the treatment. Hypertonic saline intravenously was also resorted to, but the patient died 84 hours after having been bitten. A very few marked features of the case was the exceedingly severe oedema of the bitten leg. (In the opinion of the reviewer all three cases should have been treated by local injections of gold chloride solution, plus measures against hæmorrhage. *Echis* venom is fairly deadly, but the chances of recovery are some 50 per cent. even without treatment, and the Lauder Brunton technique of incision of the wound and rubbing in of permanganate crystals has been shown experimentally by Acton and Knowles, and independently by Surgeon-General Bannermann, to be practically useless.)

On the other hand A. C. Bharadwaja records an interesting case of recovery after cobra-bite. A woman aged 25, was bitten on the left index finger by a

cobra, and was treated by a *madan*, who also caught the cobra. After she was brought to hospital severe symptoms and unconsciousness set in, together with paralysis of the muscles of the face and tongue. She was treated with strychnine injections, incision of the wound and rubbing in permanganate crystals, and 10 c.c. of Fitzsimson's polyvalent antivenous serum (prepared in South Africa) given intravenously, followed later by a repetition of the same dose. The patient recovered.

Research work on antivenene under the Indian Research Fund Association was continued during the year. The Rev. Father J. F. Caius and the Rev. Father A. Steichen, S.J., report that the absorption spectra of antivenene and of normal horse serum are practically identical and do not point to any essential difference between the two. Major L. A. P. Anderson and Father Caius have studied the effect of storage on the potency of antivenene. It gradually loses its potency over the first six to nine months. Thereafter, curiously enough, its potency increases, especially at 12 to 14 months' storage. Light and heat at ordinary room temperature exercise no appreciable influence on its potency. Captain C. de C. Martin reports that formalin diminishes the toxicity of both cobra and Russell's viper venoms and that this action of formalin is increased by heat. Heat *per se* does not, on the other hand, increase the potency of these venoms. A dilution of 0.1 per cent. of formalin diminished the toxicity of cobra venom to animals seven or eight-fold, and that of Russell's viper venom three-fold.

MISCELLANEA.

A number of miscellaneous papers in connection with general medicine call for review. In connection with *nephritis*, Major E. H. Vere Hodge comments on the staphylococcal kidney in childhood. The kidney appears to be especially vulnerable in childhood, and four illustrative cases are cited. Acetonuria is frequently present, and often severe antecedent tonsillitis. On culture of a catheter specimen of the urine staphylococcus, either with or without *B. coli*, is found. By way of treatment, a mixture containing hexamine, acid sodium phosphate, sodium benzoate should be given, and large amounts of fluids. The throat should always be examined. The condition is sometimes afebrile, but more usually febrile, and may be acute, and with convulsions—possibly due to the acetonuria. S. C. Bose further records the case of a European female aged 38, with acute synovitis of the left ankle following upon a severe attack of follicular tonsillitis; there were no renal symptoms, but examination of the urine showed copious albumin and some blood; hæmolytic streptococci were isolated on culture of a catheter specimen. Dr. A. Neave Kingsbury and K. Kanagarayer describes a modification of Goré's method for the rosindole reaction as applied to the urine, the cotton-wool plug of Goré being changed for filter paper, and a standardisation of the test introduced by the use of filter papers dipped in solutions of neutral red of different strengths. They conclude that a positive result does not indicate the presence of indican in the urine; that the percentage of positive cases is decreased in nephritic cases and increased in cases of liver insufficiency.

Dr. U. P. Basu deals with *heart diseases* as observed in Bengali patients, contrasting his experiences at Dr. Lewis' clinic in London with those in Bengal. Heart diseases, as seen in Bengal, are very different from those seen in Europe. Chronic endocarditis, mitral disease and aortic regurgitation are rare in India, in contra-distinction to their frequency in Europe. On the other hand, acute infections of the heart appear to be commoner in India, such as follow influenza, puerperal sepsis and other acute streptococcal infections. Angina pectoris, as a lesion of the coronary arteries, is rare, but anginal symptoms, due to exhaustion of the cardiac muscle, are not uncommon. In the tropics diseases of the myocardium, rather than of the

endocardium and pericardium, appear to predominate. This may be correlated with (a) the poverty-stricken diet of the Indian *ryot*; (b) the special incidence of acute fevers of different sorts such as malaria, kala-azar and the like; and (c) viscerotoposis. In brief, the problems of cardiology in Bengal differ in toto from those in Europe and deserve differential study.

Of diseases of the central nervous system, Dr J. P. Cullen records a case of muscular dystrophy of scapulo-humeral type, and Major J. B. Hance one of pseudo-hypertrophic type in a Pathian boy aged 8 years. These diseases are not uncommon in India, and their relative frequency perhaps calls for investigation. With regard to mental diseases, Dr. F. Noronha deals with dementia praecox as seen in cases in Bangalore Asylum. Some 20 to 30 per cent. of patients admitted to asylums in India come under this head. In the majority of cases there is a history of the patient having run away from home, and having in the course of his travels come into collision with the law. Irregularity of conduct is often the first great cardinal sign of the disease; and many such cases wander at large throughout India, attaching themselves to pilgrim or wedding parties or being present at fairs and festivals. The phase of vagabondage is often preceded by one of dislike of parents or house-relatives. On admission, such patients are often quite docile, their memory for events quite good, but their emotional instability is shewn by their senseless laughter or purposeless smiles. Within a few days of admission the patient has declared the true nature of his malady; he has either snatched another patient's food, or torn his clothes to rags, or soiled himself or the floor and walls of his room with faeces. Bizarre conduct plus clear consciousness and good apprehension of surroundings with often a good memory, serve to distinguish these patients. Many patients exhibit a condition of negativism, in which they refuse to take any interest in their surroundings, become completely apathetic and even dumb. By way of treatment suitable occupation is the first great line of treatment. The general practitioner in India would do well to recognise the considerable frequency of the disease and to learn how to diagnose its early symptoms.

Major O. A. Berkeley-Hill pleads for the introduction of familial treatment of the insane, and describes the interesting results obtained by this line of treatment at the little town of Gheel in Belgium. Here, amid a population of some 15,000 persons some 1,500 mental patients are boarded out with different families; the medical supervisor selecting where the patient should stay and with whom. The average cost per annum works out at only some Rs. 85 per year per patient, and results are good. Restraint has rarely to be inflicted. He considers the method suitable for introduction into India.

In a note upon *otorrhoea*, S. N. Consul advocates the use of acriflavine for this common complaint. The meatus should be syringed with a 2 per cent. solution (grs. 11 to the oz.); cleansed with hydrogen peroxide; and a few drops of pure acriflavine instilled, and a cotton wool plug inserted. In 11 cases out of 12 the results are successful.

In connection with *oriental sore*, D. N. Basu records an interesting case seen in Calcutta. The patient was a Hindu girl aged 5, who had been in the Punjab 6½ to 7 months before the sore appeared, a fact which appears to fix a definite incubation period, since oriental sore is not indigenous in Calcutta. *Leishmania tropica* was demonstrated in films from the sore and in its herpetomonad form in cultures; in these cultures a very few post-nucleated forms were seen, with the micro-nucleus posterior in place of, as usual, anterior to the macro-nucleus, these forms rather recalling the posterior nucleated forms described for *Trypanosoma rhodesiense*.

PHARMACOLOGY.

A considerable number of papers call for review. Major Chopra and Dr. Sudhamoy Ghosh comment on

the use of buffered solutions for perfusion of isolated organs. Ordinary Ringer's and Tyrode's solutions are unsuitable on account of their wide pH range under experimental conditions. Fleisch's solution is recommended, as its pH variation is so slight as to be negligible, and the stock solution keeps indefinitely in paraffined bottles in the tropics. Majors Acton and Chopra deal with the influence of the pH on the activity of pressor bases, and find that in general such bases act best at about the neutral pH of 7. These bases act (a) on sympathetic nerves or involuntary muscle, causing contraction or relaxation; (b) they may increase or diminish cell permeability. In different species of animals the same amine may produce quite different results; e.g., in one animal contraction, in another relaxation, in a third relaxation followed by contraction, in a fourth inhibition. Some volatile amines act best as bases; other non-volatile amines act best as hydrochlorides at a pH of 7. Further the pH of different tissues of the body varies and the defensive action of the liver against such bases is important; disease following perhaps only in such patients as have a defective liver mechanism. These factors are intimately bound up with the individual idiosyncrasy shewn in such diseases, as asthma, urticaria and giant urticaria, and epidemic dropsy and beriberi.

The use of *digitalis* in tropical medicine has been the subject of papers during the year. Major Chopra, Dr. S. C. Bose and P. De conclude that both biological and chemical assays shew that tincture of *digitalis* undergoes rapid deterioration in the tropics. Further, this deterioration cannot be accurately estimated by such methods as Hatcher's "cat method," the "frog method," or Kundson and Dresbach's chemical method. Clinical tests give the most reliable information. The average dose of 15 c.c.—or 4½ drachms—of tincture per 100 lbs. of body weight required to get the patient under full *digitalis* effect is considerably increased with tinctures which have been even for a short time exposed to tropical conditions.

The deterioration is due to some change, as yet but little understood, in the glucosides in the tincture. The doses of tincture of *digitalis* usually employed by practitioners in the tropics—i.e., from 5 to 15 m. t.d.s.—are quite useless; with ordinary tinctures a dose of 20 to 30 m. t.d.s. should be given, or if a rapid effect is wanted, 45 to 60 m. t.d.s. Signs of *digitalis* intoxication, such as vomiting, are so rare that no hesitation whatever should be felt in pushing the doses to the extreme in critical cases.

Dr. S. C. Bose returns to the same subject in a clinical study of 150 cases of cardiac disease studied in Bengal. Of these cases only 6 per cent.—as against over 66 per cent. in European cases—shewed auricular fibrillation. The average quantity of *digitalis* tincture needed to produce toxic symptoms was in Europe from 4 to 7 drachms, in Calcutta from 14 to 29 drachms. To obtain prompt results in grave cases in India the tincture should be given in doses of from 2 to 3 drachms per day for 5 days. The cases which respond best are those of failure with normal rhythm, senile hearts, marked hypertension, and fatty degeneration of the myocardium; cases of aortic regurgitation and syphilitic myocarditis do not respond so well. The toxic effects are chiefly slowing of the heart rate to an alarming degree, vomiting and diminished diuresis; but they are rarely seen with doses of less than 2 drachms per day for 7 days. A *digitalis* tachycardia has been noticed as a sudden paroxysmal phenomenon in a few patients. The same author, in a later contribution, states that he has found P. D. and Co.'s "Digifortis" preparation to retain its full potency in the tropics; with this preparation a total daily dose of 1 drgm. may be given until the patient is under the full *digitalis* effect.

Quinine has also come in for considerable attention during the year. Major J. A. Sinton gives a clinical method for estimating the amount of quinine in medicinal solutions, which will enable the practitioner to

estimate whether the quinine mixture prescribed and made up is up to strength or not. Any albumin present should be removed from the fluid by boiling with a little acetic acid; and 4 c.c. of the fluid diluted with 246 c.c. of distilled water. Of this take 1 volume and add 1 volume of Tauret's modification of Mayer's reagent. Compare the opalescence produced against a set of standard opacity tubes of Brown (as employed in vaccine preparation), or make up a set of standard tubes of known quinine dilutions as a control.

Majors Acton and Chopra have studied the concentration of quinine in the circulating blood. The administration of alkalis before giving quinine almost doubles the absorption of and percentage of quinine in the portal blood stream. The rate of quinine absorption is less in an acid substrate, such as the stomach, than in an alkaline one, and also if gastritis be present. The markedly greater concentration in the portal than in the systematic circulation after administration is probably due to the "barrage" action of the liver in adsorbing quinine. Treatment with quinine plus alkalis increases the cure rate in malaria chiefly on account of the increased absorption of quinine from an alkaline substrate. Quinine is especially effective in malignant tertian malarial infections, since its zone of greatest concentration in the portal blood stream coincides with the site of most active multiplication of the parasites in the same area. The rate of absorption of quinine is dependent upon physical laws; it is great if excess of $-OH$ ions be present, defective if excess of $-H$ ions be present.

Major T. A. Hughes comments on the effect of quinine administration on the blood-sugar. Hyperglycemia is produced in rabbits by large doses of quinine, and the effect of insulin on this condition is similar to its effect in adrenalin hyperglycemia. Ergotoxine, and to a less extent pituitrin, inhibit the glycogenolytic action of quinine. Quinine in anti-malarial doses causes a lowering of the blood-sugar in man, and this effect can be neutralised by pituitrin injection. Mild symptoms of hypoglycemia may ensue after quinine administration. These can be prevented by giving carbohydrates or a meal rich in carbohydrates half to one hour before the quinine dose is given. (It will be remembered that in Dr. Bishop's cinchona febrifuge formula given on page 2 of our annual review-supplement for last year, 10 grains of cinchona febrifuge are prescribed in half an oz. syrup.)

A very interesting discussion took place at the Royal Society of Tropical Medicine and Hygiene in December 1924, on *drug addiction in the tropics*, and is reported in the Society's *Transactions* for 1925. Professor W. E. Dixon, F.R.S., spoke of the physiological aspects of drugs of addiction; drugs so defined must either cause a great stimulation of the relatively lower cerebral centres; or they must selectively cut out the higher faculties of the mind. The Opium Commission in India in 1895 concluded that, contrary to opium having an evil effect upon the population, it tended to ward off sickness and lessened the discomfort consequent on poor food and malarial and other diseases. Opium smoking was the least objectionable form of opium habit, since the amount of alkaloid absorbed is small, and this type of opium habit is the easiest to cure. The abolition of opium export from India to China has achieved no good result; on the contrary Japan has stepped in with an ever growing opium trade, opium was now more extensively cultivated than ever in China, which had also tasted the far worse pleasures of heroin and morphine. Heroin is a terrible drug; its use is not necessary to the physician, and it should be prohibited. With regard to *Cannabis indica*, it was curious that the plant grown in Siberia did not shew the toxic properties of the Indian variety. This drug was not as dangerous as was commonly supposed; it produces exhilaration and is taken to overcome fatigue, physical or mental. D. D. Cunningham in India had a monkey which became so habituated to this drug that he resisted all attempts to remove him from the chamber in which

its fumes were administered to him, and on days when the treatment was omitted he became restless and uneasy. In India the cocaine habit is largely confined to opium and *ganja* addicts, and it is taken in the form of tablets or powder, chewed with betel leaves and slaked lime. It is the most terrible of all habit-drugs.

Major-General Sir Havelock Charles (retired) said that he saw no more harm in the use of opium in moderation than in that of alcohol or tea under similar circumstances; he had known Indian troops who were confirmed opium eaters to cover very long marches under very trying conditions without discomfort. Abuse could not be defended, of course, but for the tea coolie and the *ryot*, when his day of heavy labour was over in the fields, a small dose of opium soothes and cheers. The insurance companies do not demand any extra premium from a moderate opium eater. Further, opium is used medicinally throughout India, and the common people are well aware of its value for intestinal disorders. Opium did not lead to crime. With alcohol the case was different; of the two he considered opium far more harmless. Dr. A. Powell summarised his observations during 32 years of service in India. The excessive use of Indian hemp was usually seen among the *fakirs*, *sadhus*, and *bairagis* pestilential parasites for the most part upon the people. Euphoria—the sense of well-being—was the objective of most hemp-addicts, but probably some 50 per cent. of *charas* takers reach the aggressive stage, become quarrelsome and may commit crime. Indian alienists are agreed that hemp gives rise to a readily recognised form of insanity and describe several varieties, of which exaltation mania is common. Of 4,700 lunatics who had passed through his hands in India, in not a single instance could the insanity be attributed to opium. If hell be populated with "opium fiends" as many good people suppose, it will be a quiet, sleepy and stupid place. The morphia habit he had only seen three times, and in all instances the addicts were Europeans; he did not know what the position was with regard to heroin, but the U. S. A. exported 166,000 ozs. annually to England, and 88,000 ozs. annually to India. Cocaine was becoming more and more serious in India. Early during the war he had experimented on a group of cocaine chewers, by offering them substitutes; none of them had any use at all for either stovaine or beta-eucaine; neither was "the real stuff."

There ensued after the reading of the papers a considerable and very interesting discussion, which considerations of space prevent our summarising. Sir T. Carey Evans, I.M.S., declared that crude opium was far safer than any other intoxicant drug in India. Whisky was the *real* evil; its importation into and consumption of in India was going up by leaps and bounds. If the League of Nations proposed to take up the drug question in India, let them first control the importation of morphine, cocaine and heroin from Japan, America and Germany, and the importation of whisky from the United Kingdom.

It will be seen that enlightened medical opinion is well nigh unanimous with regard to the use of opium in India; it is the poor man's solace and the labourer's friend; the real evils are connected with the other drugs. (On the other hand the reviewer would like to add one point which seems not to have been noticed during the discussion; the indiscriminate custom of *ayahs* and Indian mothers of administering opium to infants in many different infantile ailments; a practice which often does very considerable harm.)

Any note on pharmacology in India during the year would be incomplete without mention of the publication in the *Memoirs of the Asiatic Society of Bengal* of the Rev. P. O. Boddington's "Studies in Santal Medicine and Connected Folk-lore." This voluminous work is the result of a lifetime almost of observation of and association with the Santals. Quite apart from its great literary and ethnographical value, it constitutes a

very important contribution to the study of the indigenous systems of medicine in India. Work such as this exhaustive memoir of Mr. Boddington is of great value in presenting in collected form materials for investigation by the experimental pharmacologist.

SURGERY IN THE TROPICS.

The output of surgical papers during the year appears to have been considerably greater than in 1924, and may be considered under several different headings.

GENERAL SURGERY.

Perhaps the most interesting paper during the year was that by S. K. Ray in the *Calcutta Medical Journal* on the surgery of the ancient Hindus. If the writings of Sushruta, circa 600 B.C., be studied, it is found that students of medicine and surgery were only admitted to the small schools maintained by preceptors under most rigid selection. Before any general surgical operation the patient was placed on light diet and purged; for operation he should be seated facing east and be firmly held. Rooms occupied by surgical cases should be fumigated with aromatic odours and decorated with flowers and garlands. The dissection of the human body was taught by clearing the intestinal contents of dead persons "not more than 100 years old," and placing the bodies to decompose on raised platforms built in calm and still rivers, the different structures being exposed in turn by repeated brushing with brushes made of roots, bark and hair. Forceps in general resembled the jaws or beaks of various animals and birds, and were used for removing foreign bodies; tubular instruments were used chiefly as specula and also for insufflation of powders; probes and scoops, straight and curved triangular needles were also used, and there were fourteen different kinds of bandages. Rhinoplasty was a common operation, and was introduced from India into Europe by Carpur in 1814. The best method for removing an arrow embedded in the flesh was to tie the shaft to the leg of a horse and then flog the animal; something was then bound to happen! Laparotomy for intestinal obstruction was practised, the incision in the gut being closed by applying the mandibles of biting black ants and cutting away their bodies. Ascites was tapped by a crude trocar. Fractured limbs were treated with bamboo splints and wooden pegs driven into the beds to keep the injured limbs in position. Hemorrhoids were treated by the local application of strong caustics through a crude speculum. In cases of vesical calculus, the stone was manoeuvred into the perineal region by fingers inserted into the rectum, an incision made, and the stone extracted. Cataract was treated by couching. In an editorial on Mr. Ray's paper, the *Calcutta Medical Journal* comments on the amazing wisdom and experience of these ancient surgeons; but we take it, although we have heard much lately of "the return to Ayurveda," that the editor of our very ably conducted contemporary does not seriously advise surgeons in the twentieth century to return to the use of the (septic) mandibles of black ants for intestinal suture, or to "horse-power" for the removal of embedded foreign bodies!

Lieutenant-Colonel H. Hallilay discusses "asepsis," as practised in present-day "aseptic surgery." The majority of high pressure steam sterilisers are too small, and in actual use are too over-loaded; also the pressure at which they are worked is too low, a pressure of 30 lbs. being necessary. To ensure absolute safety and certainty it is most desirable to provide every steriliser drum with a cheap and efficient pyrometer. Such a pyrometer is to be found in a small packet of flowers of sulphur, sealed up, placed inside the centre of the drum and with a black thread attached by which it can be extracted when the drum is withdrawn from the steriliser and opened. Powdered

sulphur melts at a temperature of 114.5°C., is unaffected by moisture, and if the sulphur packet in the centre of the drum be melted, the operator may be certain that everything inside the drum has really been sterilised. If such a precaution be not used, one may get the drum exposed, e.g., to temperatures of 121°C. with a temperature of only 97°C. in the centre of the dressings within the drum. A set of rules should be drawn up, framed and hung up in a conspicuous place in the sterilising room: these should prescribe in the simplest possible language the pressure at which each steriliser should work, the duration of exposure, and the number of articles to be placed within the steriliser. "It is easier for a rich man to enter into the Kingdom of Heaven than for dressings at the centre of a tightly packed drum to be sterilised." After an exposure of 30 minutes to a temperature of 129°C., the temperature in the interior and centre of the drum rose to only 117°C., with a lag of about 12 minutes in time. Anthrax and similar spore-bearing bacteria are not killed at 10 minutes exposure to 115°C.

The same author also comments on the treatment of incisional sinuses. Such septic sinuses are common in this country, especially in connection with abdominal wounds, and often the patient's mental condition after perhaps years of suffering is a pitiable one. In treatment the first step is to lay open the sinus along its whole length. All instruments used in doing so are now discarded, and fresh ones used in the second step. The ribbon of granulation tissue lining the sinus, together with the surrounding wall of dense scar tissue is next removed, if possible *en masse* in one piece. A third set of fresh instruments is next used to take away a thin slice of the apposing surfaces of the wound, which are then cleansed, swabbed with tincture of iodine, and sutured. No vessels should be tied and no suture materials left in the depths of the wound. Illustrative cases shew the rapid healing which takes place by first intention and the excellent results.

J. K. Datta describes with numerous illustrations and x-ray photographs, the technique for operative treatment of chronic frontal sinus suppuration. Two cases are cited, one of them associated with syphilitic infection. The adjacent ethmoidal cells must be dealt with. P. K. Bardhan advocates Pezzar's self-retaining catheter for the drainage of empyema, with the use of the thumb and ball of the thumb part of a sterilised surgical rubber glove glued to it with surgical sterile glue. After insertion of the catheter, this rubber surface is then glued to the skin surface with surgical glue, and provides an air-tight adhesion.

INTESTINAL SURGERY.

Colonel Hallilay discusses the operative treatment of intestinal stasis, describing and warmly advocating Sir Arbuthnot Lane's technique, which he has studied under that pioneer. After laparotomy the whole bowel is surveyed, and any bands or kinks tying down the pelvic colon are divided, and the cut surfaces peritonised. Bands at the lower end of the ileum or a controlling appendix may next require division or removal. The results are remarkably good, even such conditions as epilepsy and sexual impotence being cured by this operation.

Captain R. V. Rajam describes a case of acute duodenal ileus in an emaciated male adult, aged 50. Diffuse abdominal pain was present but no rigidity; there was an abdominal facies, tenderness over the whole abdomen, pulse 110, temperature sub-normal. At operation an immensely distended stomach and duodenum were found and a collapsed ileum. The patient died 48 hours after operation, and the condition was probably due to pressure of the superior mesenteric vessels crossing over and compressing the terminal portion of the duodenum. M. E. T. Chelram describes the case of a male Sikh, aged 30, with volvulus of the ileum, 40 inches of the lower end of which was found to be gangrenous. Primary resection of 42 inches of gut was performed, the caecal end of the ileum closed,

and its proximal end anatomosed to the side of the cæcum. The patient not only recovered, but was also spontaneously cured of a reducible right inguinal hernia previously present. The symptoms present were extraordinarily slight, despite the very grave condition found at operation; there was hardly any vomiting, temperature 99.4°F., pulse 82, rising before operation to 102. Operation was performed 33½ hours after the onset of the first symptoms. J. B. Vaidya gives an account of a case of acute intestinal obstruction due to hernia into the fossa duodeno-jejunalis, with death on the third day after operation from heart failure.

With regard to *appendicitis*, Major A. G. Tresidder calls attention to an unusual sign in retro-cæcal appendicitis; the patient adopts a prone posture lying flat on his face and abdomen, as this is the only position in which he is comfortable. Rai Sahib Mukand Lal of the Dufferin Civil Hospital, Delhi, draws attention to the frequency of appendicitis; 15 cases have been seen at that hospital in the past year. He advocates the use of a 3½ per cent. solution of picric acid in alcohol for skin sterilisation, and silk for all sutures except for those for the skin incision.

With regard to *hernia*, A. B. de Castro describes an extraordinary case of pseudo-hernia. A military police constable suffering from colicky abdominal pain applied a heated brass *lotah* over his umbilicus, on the advice of his friends, and was subsequently quite unable to remove it. Under chloroform anaesthesia the bottom of the *lotah* was removed with a chisel and hammer, but its top still remained fixed. Inside it was found an engorged, dark-blue mass of flesh. A crucial incision was made into this mass, which consisted of the whole thickness of the abdominal wall and some omentum, whereupon the *lotah* came away. The incisions were then cleansed and sutured and healing took place by first intention. P. Chatterji describes a case of post-peritoneal hernia in a Hindu male, aged 28, with symptoms of a strangulated left inguinal hernia. At operation a peritoneal opening was found 2 inches above the level of the internal abdominal ring and ½ an inch outside the lateral margin of the rectus sheath. The small intestine had herniated through this and then into the inguinal canal. M. N. S. Chetti describes a case of a partly descended testis gripped at the external oblique ring with symptoms of hernia: operation resulted in cure. The same author also records a case of acute gangrene of the testis from acute torsion of the spermatic cord, without apparent cause.

With regard to *hemorrhoids*, Captain D. R. Kehar advocates treatment by strangulation and snipping, on a study of some 300 cases. Before operation castor oil is given and enemas, a milk diet for 24 hours, and the parts painted with tincture of iodine. After exposure of the piles a half-curved needle 1½ inches long is threaded with No. 3 or 4 catgut suture thread. Loop sutures are applied above and below the base of the pile, which is snipped off after being strangled. A vaselined rubber tube is inserted and removed next day, tincture of perchloride of iron and tincture of opium being used as local applications. For 4 days the patient is given a milk diet, on the fifth day castor oil, and he is usually ready for discharge about the seventh or eighth day.

SURGICAL TUBERCULOSIS.

This has been the subject of numerous papers during the year. Lieutenant-Colonel E. W. C. Bradfield contributes a very striking article, beautifully illustrated, on abdominal tuberculosis in Indian practice. At the Madras General Hospital in 1924 cases of surgical tuberculosis admitted numbered 205, or 2 per cent. of all admissions, and 95 of them were cases of abdominal tuberculosis; a far higher figure than obtains in Europe. With regard to tubercular peritonitis two types can be recognised; (a) the ascitic type, which is comparatively rare; and (b) the fibrous-adhesive type, which is common, and of which 40 cases were operated upon. In this the symptoms are abdominal pain, fever,

and sometimes the presence of a tumour-like mass with visible peristalsis due to chronic intestinal obstruction. The pain is never of the recurrent, periodic character that marks gastric or duodenal ulcer. Operative results are, as a rule, poor. Of tuberculosis of the cæcum 20 cases were seen during the year. Again two types may be recognised; (a) an entero-peritoneal type, which is an ulcerative caseous tuberculosis attacking the cæcum, ileum and appendix, with the lungs frequently also involved, intestinal fistulae common, and with signs of enteritis and not of obstruction. (b) The hyperplastic variety, simulating a neoplasm in the right iliac fossa. This is of insidious onset with fibrosis, thickening of the cæcum walls, and increasing symptoms and signs of intestinal obstruction. It occurs at from 25 to 35 years of age. The operative treatment consists in excision of the cæcum, when possible, and lateral anastomosis of the ileum to the transverse colon. Results are on the whole good, although the Indian patient is usually seen at a very late date and tends to be a bad surgical risk. A rare variety of intestinal tuberculosis is that of the jejunum with symptoms simulating duodenal ulcer.

Dr. E. F. Neve also calls attention to the hyperplastic type of tuberculosis of the cæcum, as thus described by Colonel Bradfield. He describes two cases associated with stricture of the ileo-cæcal valve and hyperplasia of the cæcum. Both proved eminently curable, the treatment being lateral anastomosis of the ileum to the lower end of the ascending colon. R. S. Grewal also deals with the treatment of abdominal tuberculosis. In cases of mesenteric or chronic tuberculous peritonitis and *tabes mesenterica* he advocates the use of oxygen inflation of the abdomen. Under local anaesthesia the abdomen is opened by a tiny incision, the nozzle attached to an oxygen cylinder apparatus is inserted and the abdomen inflated; the opening being finally closed by a purse-string suture. The oxygen is absorbed within from 12 to 36 hours; results in six cases so treated were good.

Our contemporary, the *Indian Medical Record* gives answers to a widely circulated questionnaire as to the incidence and treatment of tuberculous glands in India, and we hope that the evidence thus collected will be summarised and published. V. G. Rele and P. V. Gharpure deal with the results of different procedures in tuberculous abscesses. Aspiration plus oxygen injection was tried on cases of tuberculosis of the hip-joint and cervical glands, but sinuses resulted. Old tuberculin ointment by inunction was tried in gland cases, a 3 to 4 months' standard treatment being given; the result was improvement. Cabot's solution—containing ether, oil of creasote, guaiacol and iodoform—was repeatedly injected into tuberculous abscesses after aspiration; with this method results were on the whole good. Sodium morrhuate given intramuscularly proved so painful that its use was abandoned.

VESICAL CALCULUS.

The tremendous importance of this subject in Indian surgery is well illustrated by the numerous papers and distinguished authors who have dealt with it during the year. Lieutenant-Colonel Henry Smith (retired) contributes notes on litholapaxy, and emphasises the value of small lithotrites in sounding for small stones, and the use of an irrigator with 4 feet of pressure. Where perineal lithotomy has to be done, the lateral operation is preferable to the median one, as it gives much more room. The mortality from sepsis in poorly-staffed and inadequately-nursed *mofussil* hospitals in India is some 40 per cent. after supra-public lithotomy—an operation which should only rarely be called for; 10 per cent. after perineal lithotomy; and but 2 per cent. after litholapaxy. For beginners, manipulative skill may be acquired by the use of a goat's bladder containing a nugget of brick, fixed to a plaster mould.

Major-General A. Hooton comments on the same question. Surgical text-books and British authors speak

of the decline of litholapaxy; yet it is the operation for India. A considerable proportion of Indian cases have large stones and septic bladders, whilst the Indian patient is far less robust than is the British one, and a much worse surgical risk. The up-country Indian *ryot* has long ago, made up his mind that litholapaxy is far better than a cutting operation, and there is no surer way of emptying an Indian hospital than by reverting to a cutting operation for stone where crushing has formerly been in vogue. The following collected figures in the practice of some well-known Indian surgeons speak for themselves:—

	Litholapaxy.		Supra-public Lithotomy.	
	Cases.	Deaths.	Cases.	Deaths.
Civil Hospital, Hyderabad, Sind. 1920-23. Lt.-Col R. W. Anthony.	1,253	7	11	3
J. J. Hospital, Bombay, 1920-23. Lt.-Col T. S. Novis.	114	1	17	5
J. J. Hospital, Bombay, 1921-24. Mr. A. K. Dalal, F. R. C. S.	13	0	8	0
Civil Hospital, Nasik, 1922-25. Lt.-Col H. J. Vernon Betts.	58	0	5	0
Agency Hospital, Rajkot. 1920-25. Lt.-Col A. Hooton.	94	2	15	0
Total ..	1532 cases with 10 deaths; case mortality 0.6 %.		56 cases with 8 deaths; case mortality 14.3 %.	

Perineal lithotomy still has its place, despite statements in text-books to the contrary; it is the operation for encysted stones and when abscess is associated with them about the neck of the bladder.

Lieutenant-Colonel R. W. Anthony comments on certain aspects of litholapaxy. The operation is easy in children as the bladder is never out of shape in them and never loculated, but it is necessary to anaesthetise deeply. A fine rubber drainage tube tied around the base of the penis is helpful, also the use of Liston's graduated metal bougies to dilate the urethra in children. In catching and crushing a stone, do not rotate the beak of the lithotrite; keep the female blade on the floor of the bladder and investigate the areas in front and behind by elevation or depression of the handle. Withdraw and then close the male blade once or twice before crushing to make certain that no mucous membrane has been included between the blades. The evacuator possesses no advantage with children; it is better to fill the bladder from a cannula and to express by pressure over the abdomen above the pubes. If the lithotrite will not lock on to a stone, tap it lightly with a hammer. Suprapubic lithotomy is indicated in some 1 per cent. of cases of calculus and perineal lithotomy in some 2 per cent.

Of individual cases of vesical calculus, Lieutenant-Colonel J. L. Lunham records the case of a stone in the bladder of a woman aged 35, found to have formed around the end of a stick 5½ inches long inserted into the vagina two years previously for the purpose of procuring abortion. The stick was found lying with its head in the bladder and the remainder in the walls of the vagina and urethra. Dr. J. W. McK. Nichols gives an account of a case which sounds a note of warning; a medical practitioner inserted an old and worn-out rubber catheter into a bladder. When he came to withdraw it, it broke, the end remaining in the bladder. Six months later the patient was operated on for a vesical calculus which had formed around

the end of the catheter. S. K. Nathan records a case of recurring and encysted calculus. A boy of 16, was operated upon by supra-pubic lithotomy for a large stone in March 1921, and in September 1924, presented himself with a hypogastric fistula through which he had voided a second stone. He was operated upon in December 1924 by supra-pubic operation when two further phosphatic stones were found in the bladder. The fistula was excised and the patient made a complete recovery. B. R. Garg records a case of vesical calculus associated with perineal fistula.

PROSTATE, BLADDER, ETC.

Lieutenant-Colonel Henry Smith (retired) draws attention to acute inflammation of the prostate, a disease which is barely mentioned in text-books, but which is one the symptoms which it is very important for the practitioner to recognise. He has operated upon as many as three cases of this condition in one morning. The disease occurs in men between 20 and 60 years of age, with rapid onset of retention of urine, perineal pain and rectal tenesmus. If such symptoms occur, the medical attendant should not hesitate to operate by perineal incision; otherwise an abscess may form and burst into the rectum or bladder. The teaching in books that a prostatic abscess which has burst into the bladder or rectum should be left alone is wrong. In either instance perineal incision and drainage should be resorted to. Acute inflammation of the prostate is *not*, in his experience, usually of gonorrhœal origin.

Dr. M. D. David advocates supra-pubic prostatectomy at one sitting for enlarged prostate. Patients should be kept under preliminary observation, catheterised regularly, the bladder daily irrigated with permanganate or boric lotion, urotropine given, and milk and barley water. Prior to operation 6 to 8 consecutive doses, each of 15 grains of calcium chloride, should be given. After shelling out the prostate, hæmorrhage should be stopped by hot irrigation of the bladder, and after operation the patient should be put into Fowler's position and supra-pubic drainage established.

S. Dutta describes a case of small diverticulum of the bladder in a male coolie aged 40, with symptoms of frequent and sudden stoppage of micturition and localised pain. The diverticulum seen through the cystoscope is illustrated in a coloured plate, but the patient refused operation.

S. C. Das Gupta comments on the frequency of carcinoma of the penis as seen in Nepal. At operation the urethra should be transplanted as low down as possible, and stricture of the urethra, requiring repeated dilatation, is not infrequent as a sequel.

ORTHOPÆDIC SURGERY.

Again a considerable number of papers call for comment,—many of them by Lieutenant-Colonel H. Halliday,—showing how very important is this branch of surgery in Indian practice. In the treatment of stiff joints, he claims, the surgical profession shews itself almost at its worst. It has adopted the methods of the bone-setter without acknowledging them, and the amount of injury which is often inflicted by forcible manipulation of stiff joints under an anæsthetic is shocking. Wounding and traumatisation of shortened muscles can do nothing but harm. What is wanted in the treatment of these cases is steady perseverance in constant massage, and passive and active and voluntary movements. The surest way of producing stiff joints is by prolonged immobilisation of joints after injury, and many such cases would never have arisen if early massage and movement had been instituted.

The same author deals with sub-periosteal excision of joints. In a case, for instance, of old standing fracture-dislocation of the elbow joint with reduction out of the question, sub-periosteal excision was followed by complete restoration of movements. The excision must be done with a sharp ruginé so that the "cambium" layer of the bone is raised together with the periosteum,

and he uses Down Bros' Ollier's ruginer with a razor-like edge. By this procedure a sufficient supply of osteoblasts is raised with the periosteum to reconstitute new bone. In the treatment of elbow-joint fractures, the same author comments on the bad and even disastrous results from putting up the fracture in full flexion, a procedure which is commonly taught. Fracture from falls at a height usually passes through the coronoid and olecranon fossa and to a variable distance above the external and internal epicondyles; the forearm, together with the attached lower fragment of the humerus being carried bodily backwards and upwards behind the lower end of the upper fragment of the humerus. Treatment by flexion and fixation means subsequent deformity and fixation in a bad position.

Colonel Halliday also deals with chronic osteomyelitis in long bones, again a subject of great importance in this country, where the condition is frequently seen. Excluding syphilis, tuberculosis, new growth and mycetoma—which together constitute the aetiological factors of a considerable proportion of the cases seen in India—the usual types of the disease encountered are:—(a) Massive necrosis of the whole shaft, chronic and following on acute osteomyelitis, with the original shaft enclosed in new bone, suppuration, and sinus formation. (b) Chronic overgrowth and sclerosis of the shaft of the bone with or without sinus formation, often with the formation of more or less large sequestra. The outstanding feature of the disease in India is its chronicity; it may persist from childhood into adolescence and even far into adult life; many patients only die after years of suffering and many scraping operations.

The surgical problem present in such cases is how to obliterate a septic cavity with rigid walls, and many different procedures have been advocated by different authors. The method described by Colonel Halliday aims at converting the cylinder of bone into a lathe, nothing but the posterior thickness of the shaft being left. An incision is made down to the bone throughout the whole length of the diseased areas. The periosteum is then carefully separated from the bone with a ruginer of razor-like sharpness, raising with it the cambium layer of bone and the bone-forming osteoblasts. Free exposure and a good light are essential. All dead bone is now excised, preferably with an electrically driven Allbee's saw. The result is a keel of healthy bone plus a periosteal sleeve. The periosteal flaps are next united along the line of the original incision and all dead space obliterated. The cavity on healing granulates from the bottom and bone re-formation is sound and not diseased. Five illustrative cases are cited.

P. C. Dutt deals with the application of extension in cases of simple fracture. An ingenious method which has been found to give excellent results at the Medical College Hospital, Calcutta, is as follows:—The limb is shaved and painted with glue containing 30 parts of water; a glue-soaked bandage is then applied to the limb, and after it laterally placed flannel bandage strips soaked in glue, to which the extension is applied. With this technique the extension does not slip, the bandages do not loosen, there are no blisters or sores, and one can always apply sufficient extension. The method is often combined with outside elastic bandages.

U. N. R. Choudhuri describes a case of ankylosis of the right knee-joint, flexed at an angle of 120°, cured by excision and synostosis in a position of full extension. The patient was cured and was able to walk with a wooden patten. P. C. Das contributes an interesting paper on left-handedness, shewing the special association of this condition with mirror-writing, squint, mental defectiveness and stammering.

ANÆSTHETICS.

Again a number of special papers call for review, prominent among which are a series by Lieutenant J. P. Arland who has been experimentally studying both

intra-arterial and intravenous anæsthesia. Intra-arterial anæsthesia was tried in dogs by injection of a 2 per cent. cocaine gum acacia solution into the femoral, abdominal aorta, common carotid and brachial arteries. Dogs stand cocaine well, and the anæsthesia produced in the areas supplied was immediate and profound, whilst no motor paralysis was observed; the anæsthesia is probably due to paralysis of the nerve endings in the area supplied by the vessel. In a monkey the pineal gland was excised under intra-arterial anæsthesia. The right common carotid was exposed and clamped; the head elevated and the neck massaged to empty the veins. A solution containing 2 per cent. gum acacia, 1 grain of cocaine hydrochloride, and 5 minims of 1 in 1,000 adrenalin solution, dose in all 20 c.c., was injected into the artery. The internal jugular vein was next clamped. Operation was conducted via a transverse incision over the occipital protuberance, and the anæsthesia was found to be very profound and the operation field bloodless. There was no shock at any time and the monkey made a complete recovery. Intra-arterial injection of apothesine plus adrenalin was tried in a volunteer in the brachial artery; anæsthesia was profound and lasted for 2½ hours with complete motor and sensory paralysis, no shock, and no bad after-effects.

Cases operated on under intravenous anæsthesia are also described. Two were patients with septic sinuses of the forearm. Here the method adopted is to bandage the arm above and below the elbow, expose the median basilic vein under local anæsthesia, and inject 40 c.c. of a 0.5 per cent. solution of apothesine against the venous flow through a cannula under pressure. The part should first be rendered ischæmic before the bandages are applied. Anæsthesia in the area between the bandages is profound and satisfactory. After operation the bandages should be relaxed slowly. Circumcision was performed in an adult under intravenous anæsthesia, the injection being given into the dorsal vein of the penis, and other cases to which the method was applied were cases of scorpion sting, amputation of the foot for gangrene, and palmar abscess. The same author, in collaboration with Captain S. G. Chavan, records the case of a patient with a scrotal hernia the size of an orange operated on under infiltration anæsthesia with a 0.5 per cent. solution of apothesine, of which drug 13 grains were used. The patient was aged 65, and a chronic bronchitic, unsuitable for general anæsthesia; anæsthesia was profound, operative conditions were excellent, and there was no shock.

Major N. C. Kapur records an amazing case of resuscitation of life after the cessation of the vital functions for a period of over 15 minutes; the operation was one for malignant growth of the larynx and the patient stopped breathing before operation was commenced.

ANTISEPTICS.

Dr. E. F. Neve extols the value of "E. C."—(Electrolytic Chlorine)—in general surgical work. He advocates for irrigation of septic wounds a 20 per cent. solution; for cleansing hands and the patient's skin a 10 per cent. strength; a 5 per cent. solution as a ward lotion; for bladder irrigation a 1 in 1,000 to 1 in 5,000 solution; for disinfection of latrines a 1 in 5,000 solution; and for sterilisation of water-supplies 3.06 m. per gallon. Details are given of tests to estimate the amount of available chlorine present.

VENEREAL DISEASES. FRAMBOESIA.

These may perhaps be most conveniently considered in this section, and together. Most important is perhaps the paper by Lieutenant-Colonel A. Denham White and Rai Sahib S. C. Dutt on toxic symptoms following the administration of organic arsenical preparations. Such symptoms usually ensue about the third day after injection and are those of brain irritability with status epilepticus, later coma, death or recovery, and sometimes after recovery, jaundice. This constitutes the

Jarisch-Herxheimer reaction, and is apparently due to a hæmorrhagic encephalitis. Two instances of this occurred during the course of 3,098 injections at Alipore in 3 years, one of them fatal. In a third case symptoms occurred on the twentieth day after a course of injections had been completed, and consisted of jaundice, status epilepticus, convulsions and death. Arsenic has a selective action on the suprarenal glands and these "nitritoid crises" are apparently associated with deficiency of adrenalin in the patient. The treatment is, therefore, to give adrenalin in large doses, e.g., 10 m. injected every 4 hours.

Other authors comment on the same problem. Captain K. Sen records 2 cases of hæmorrhagic encephalitis following novarsenobillon administration. Y. S. Row describes a case of acute fever and urticarial rash 3 days after neosalvarsan administration, with recovery. V. N. Deuskar describes a case of intense urticaria and paroxysmal coughing following intravenous administration of "914." This ensued after the second injection, following on 7 months of hectic syphilitic fever. Adrenalin and intramine were given, followed by potassium iodide and a course of 8 subcutaneous injections of sulfarsenol. At the fourth such injection there was persistent vomiting and colic; at the sixth and eighth injections paroxysmal cough and severe urticaria followed. This patient was clearly intolerant to organic arsenical compounds.

Rai Sahib S. C. Dutt gives the results of an investigation into the relative values of the Sachs-Georgi and Wassermann reactions in a series of 125 patients observed at the Voluntary Venereal Diseases' Hospital (for women) at Alipore. The results of the two tests agreed in more than 90 per cent. of cases. In sending in serum for test, it should be free from turbidity and from red blood corpuscles. If the readings are doubtful, the tests should be repeated. A positive Sachs-Georgi reaction means syphilis, but occasional cases of syphilis may give a negative reaction.

For the treatment of gonorrhœa in the male, S. Chatterjee advocates the use of "Arthigon by improved process" intravenously, together with local treatment.

Frambæsia has aroused some attention during the year. In this connection priority must be given to the paper by Dr. G. C. Ramsay on the influence of climate and malaria on yaws. The disease is more prevalent among the hill-tribes of Cachar than among dwellers in the plains, and the lesions seen are typical. The effect of climate on this disease is remarkable. During the cold season it is very rare to see a case presenting typical yellow-encrusted excrescences, but condylomata, worm-eaten dermatitis of the palms and soles, and painful joints are seen. As soon as the weather gets warmer, typical yellow-encrusted yaws is again seen, and with the advent of the rains the painful plantar lesions. Heat and moisture, in other words, appear to modify yaws, and during cold weather months the disease closely simulates syphilis. In his experience of over 1,000 cases the only tertiary lesions seen were chronic dermatitis of the palms and worm-eaten like lesions of the soles. Secondary infection of yaws' lesions with Vincent's infection converts the typical frambæsal ulcer into typical, sloughing, fetid "tropical ulcers."

What accounts for the comparative mildness of tertiary syphilis, and the relative absence of parasyphilitic diseases in Cachar? Not climate *per se*, since other authors such as Spittel and Powell describe them as prevalent in the much of Ceylon and Fiji respectively. Powell mentions cases where severe or repeated malaria appeared to cause typical yaws to subside. There is some evidence, in brief, that, whilst induced malaria is to-day a standard treatment for general paralysis of the insane, tabes and parasyphilitic diseases, the incidence of malaria may also profoundly affect the symptomatology and lesions in yaws.

Major F. A. Barker records a case of yaws imported into the Andaman Islands from the Nicobar Islands, with demonstration of *T. pertenue*. Yaws is apparently endemic in the Nicobars. M. A. K. Iyer draws attention to the prevalence of yaws in Travancore. Assistant Surgeon P. Bell, I.M.D., draws attention to the incidence of yaws in the Chin Hills of Burma. He describes numerous cases of patients with the primary chancre almost always extra-genital and usually on the anus, sometimes on the labia majora in women, and sometimes in the groin in men. Novarsenobillon treatment was far more successful than it would have been in cases of syphilis.

MISCELLANEA.

With regard to *tetanus*, M. A. K. Iyer advocates the injection of repeated small doses of anti-tetanic serum, of 1,500 units daily, in place of single massive doses, as being equally efficacious and less costly, and gives two illustrative cases. P. D. Samuel records two cases treated by daily injections of 25 minims of a 25 per cent. solution of magnesium sulphate, together with daily injections of 15 minims of a 1 per cent. carbolic solution; the injections being given alternatively morning and evening.

K. P. Lahiri advocates "Hæmoplastin" (P. D. & Co.), in the treatment of chronic intractable hæmorrhage, the dose given being 2 c.c. daily subcutaneously for four days; two illustrative cases are cited.

Air embolism is dealt with from the experimental point of view by Assistant Surgeon A. R. D'Abreau, I.M.D. On experimental intravenous injection of air into the veins of animals, he comes to the following conclusions. A few small bubbles of air injected at a slow rate are harmless. To produce the death of a bull weighing 500 lbs. a dose of 682 c.c. of air had to be injected rapidly, and estimating from this, a man weighing 10 to 11 stone would require about 170 c.c. of air as a lethal dose (the dose being measured by volume and not by weight). Symptoms commenced with a bull when 227 c.c. had been injected, and working on this calculation, a dose of 64 c.c. might be unsafe for man. In diseases such as cholera, where the specific gravity of the blood is increased, air injection would prove more dangerous. Also presumably in intravenous infusion after severe hæmorrhage. On the whole, however, it cannot be said that a small air embolus injected from a syringe during the usual intravenous administration is dangerous.

Captain D. R. Kehar advocates treatment of *varicose veins* of the leg by an occlusion operation. The vein is rendered prominent by a tourniquet, and gripped by Wakley's fenestrated artery forceps. A needle threaded with No. 5 silk ligature thread is passed through the skin under the vein and round it, and tied so as to occlude the vein. This is repeated at half to three-quarters of an inch intervals from above downwards along the whole course of the vein. The vein subsequently shrivels up and ulcers heal.

Reports on the use of *iodine intravenously* continue to come in, many of them not suitable for publication. Assistant Surgeon C. P. V. Shunker, I.M.D., however, records interesting figures for its use in an epidemic of influenza at Bellary Central Jail. The formula which he adopts is iodine 1 dr.; potassium iodide 1 dr.; water 5 ozs. 2 drms., so that 20 minims is approximately equal to half a grain of iodine. This is given in doses of from 20 to 40 minims diluted with 10 c.c. of saline. Excellent results are reported. S. N. Datta also advocates intravenous iodine in cases of lobar pneumonia and cellulitis.

Many individual surgical cases of interest are reported, and it is in this field especially that opportunities occur to the surgeon in India which his professional brother in England seldom gets. Dr. H. M. Handle records the case of a child, aged 3½, who swallowed a small metal corkscrew of the type attached to a patent medicine bottle, a little over an inch in length. He was given an ounce of castor oil

three-quarters of an hour later, and fed with bulky meals of rice and bread; 63 hours after the accident the corkscrew was passed per rectum intact in the interior of a solid stool. Dr. H. J. H. Spreadbury records the fate of a pedunculated papilloma of the tongue; the patient refused operation and a ligature was applied to the pedicle; the papilloma sloughed away and the patient swallowed it on the fifth day. P. Pant records a case of unnoticed gunshot wound of the left ankle; a policeman pursuing a dacoit stumbled and fell; next day his ankle was found to be very swollen and painful; x-ray examination showed shot lying above the left internal malleolus, which was removed and the patient recovered. A curious accident to a child of 10 is recorded by P. Chatterji; the patient climbed on to a chair to reach down a book from a high shelf; he fell and caught the front of his neck on the edge of the back of the chair. Urgent dyspnoea, cyanosis and surgical emphysema of the neck set in, the trachea having been forcibly ruptured. Tracheotomy was immediately performed and a tube inserted; the patient was discharged cured on the eighteenth day.

Major J. B. Hance records four interesting cases. The first was one of extreme hydronephrosis of the left kidney, the swelling occupying half the abdomen and of 25 days' duration following an attack of renal colic. A drainage operation was followed by blood transfusion, but the patient died. A woman of 20 had an abortion at the fourth month, subsequent to which a rounded supra-pubic tumour formed with colicky abdominal pain; operation disclosed a large chylous or semi-chylous cyst between the layers of the mesentery of the small intestine, extending down into the left iliac fossa and pelvis and compressing the whole length of the colon. At laparotomy the cyst was tapped and marsupialized, but the patient died from shock. A third case was one of scirrhus carcinoma of the breast in a Mahomedan male aged 60. A fourth was a case of chronic tuberculous mastitis in a ten-days' nursing mother, the condition being more acute than the corresponding one seen in European women. The baby was saved by bottle feeding.

Miss Emily G. Stuart records a case of encephalo-meningocele in an infant at the root of the nose—a rather unusual site. Operation was followed by death three weeks later. N. S. Narasimhan describes a curious case of contracture of the mouth simulating gangosa. There was syphilitic infection of the genitalia, also possibly of the lips, with a strongly positive Wassermann reaction. Sodium antimony tartrate was given intravenously and the lips re-formed by operation. The case may have been one of mixed infection with syphilis and infective granuloma.

HYGIENE AND PUBLIC HEALTH.

Lieutenant-Colonel J. D. Graham, Imperial Public Health Commissioner with the Government of India, writes as follows:—

"As regards public health in India the situation remains very much the same as described in the *Indian Medical Year* of 1923 and 1924. In that of 1924 I hinted at the crystallisation and concentration of certain health activities with the Central Government. Such activities as international, national, and inter-provincial public health, overseas pilgrim traffic, quarantine, major port control, epidemiological information, emigration and immigration continue to be the legitimate concern of the Central Government.

"The proposal of the League of Nations to establish an Epidemiological Bureau in Singapore was accepted by most of the Asiatic Governments, and the details concerning its creation were worked out by a representative, International Committee which met under the presidency of the League at Singapore from 4th to 13th February, 1925. I had the honour to represent British India, while representatives from British

North Borneo, Ceylon, China, the Federated Malay States, French Indo-China, Hongkong, Japan, Netherlands' East Indies, Philippine Islands, Siam and the Straits Settlements were present. Lieutenant-Colonel Norman White (retired) of the Health Section of the League, a predecessor of my own, presided. As a result of the munificence of the Rockefeller grant of \$125,000 the initial financing for the first three years was assured without calling for individual Government contribution. The machinery of the Bureau was arranged, a budget estimate for 1925-26 drawn up, a Director and Assistants appointed, and the scope of the work determined. These have been embodied in the report of the Conference, whose resolutions give the salient points.

"The Conference proposals were accepted by the League of Nations and the Bureau started functioning at the beginning of April. It deals with the collection and dissemination of epidemiological intelligence throughout the Eastern arena, that is the quadrangular area of which the four gates are Port Said, Cape Town, Yokohama and Sydney. The preliminary work of the Bureau has dealt exclusively with the incidence and spread of plague, cholera, and small-pox throughout the ports of the Eastern arena, and weekly information thereon is now received telegraphically and by wireless from about 50 ocean ports in every part of this area. The organisation is proving of practical value to the countries concerned and is partly rendered feasible financially by the adoption of a code especially devised for the purpose. I will illustrate how it affects India. My office telegraphs on Wednesday of each week to the Bureau at Singapore the infectious disease condition of the major ports, i.e., Calcutta, Bombay, Karachi, Madras, Rangoon and Negapatam. Each country does the same. These reports are consolidated and telegraphed to Saigon (Indo-China) on Thursday evening, whence they are broadcasted for the East by the powerful Saigon wireless. They are picked up at Jutogh, near Simla, on Friday, passed to my office and thence to our ports on Saturday, so that Port Health Officers on each Saturday receive information regarding all the major ports of the Far East up till the previous Saturday mid-night.

"The Bureau International d'Hygiene Publique meets for ten days twice each year in Paris. Owing to the re-organisation consequent on the creation of the Health Section of the League of Nations, the Office International has been constituted the Advisory Committee of the Health Section of the League. In previous years India has seldom been represented by her Public Health Commissioner and usually by a retired officer who on many occasions might be quite out of touch with current Indian public health matters. The Secretary of State for India has pressed for the deputation, at least once a year, of the Public Health Commissioner. I accordingly attended the meeting in Paris in April—May 1925 at which delegates from 34 countries were present. The *ordre du jour* gives an idea of the subjects considered, chief of which was the proposed revision of the International Paris Sanitary Convention of 1912. I received a very cordial welcome and was able to speak to the Committee both on questionnaires which had been circulated and on public health matters of general interest. Our Kala-azar plague for 1924, the fauna of rats and their parasites, tabes and general paralysis were all dealt with.

"In my report to the Secretary of State I suggested that much might be reproduced for the Committee's consumption from amongst our research work showing our progress in India. Japan seemed to realise the value of this. A judicious selection of one or two papers for each meeting together with a research bibliography at one meeting would help the foreign delegates to realise the amount of work which was being accomplished in this country.

"I attended for several days a technical conference at the Ministry of Health between British representatives

and representatives of the Dutch Netherlands Government in connection with the adjustment of certain international difficulties which had arisen at our quarantine station of Kamaran in the Red Sea.

"Owing to divergence of opinion regarding the necessity or otherwise of a special draft Convention or new section in the Paris Revision dealing with the Far East, the International Sanitary Conference convened by the French Government for October 1925, was postponed until May 1926, to allow of proposals such as those put forward in Dr. Norman White's draft Convention and in the Pan-American Code being thoroughly examined.

"The results of the Port Administration Conference held at Delhi in November 1924, are not yet apparent. The general sense of the local governments was obtained on certain cardinal points, and, as much legislation will be necessary, matters have begun to move in certain definite directions. That of port quarantine will in due course come under scrutiny.

"The provincial decentralisation has not been in operation long enough to allow of the creation, on its merits, of a more powerful federal health organisation than at present exists; but, as I mentioned last year, such an organisation must in time be faced."

Colonel Graham's letter is of great interest. It echoes the dominant note in both public health matters--as in general policy--of the ending of the old-time policy of nationalism and the beginning of the new era of internationalism. Public health can have no frontiers, save that of a united war front against epidemic and preventable disease, and under theegis of the League of Nations, with regard to public health matters India has both great privileges and grave responsibilities. We are glad that she was so ably represented at the conference of the Bureau International, and that she has taken her share in the foundation of the new Bureau at Singapore. Fortunately Rockefeller munificence has enabled the foundation of the Bureau and brought it into being; Colonel Graham's speeches at the Singapore Conference lead one to hope that, if necessity arises, the Government of India will see to it that the Bureau shall not fail for want of support. "The readiness with which the Administrations represented at the Conference have promised their full co-operation in the working of the Bureau on the lines proposed, may be taken as an index of their appreciation of an organisation designed to secure international co-operation in safeguarding the public health of the East." runs a paragraph in the final resolution at the Conference. A study of the minutes of the Conference shews how large a share was taken by Colonel Graham himself in creating and working out plans for the efficient organisation and running of the new Bureau. At the meeting of the Office International in Paris, Colonel Graham drew special attention to the very interesting position now reached by workers in India with regard to the kala-azar transmission problem, whilst his presence as India's representative led to the dissemination of knowledge at the meeting regarding medical research work and public health policy in India generally. In brief, we can no longer visualise India in matters of public health policy as standing aloof from and outside general world movements, but as now one of the comity of nations.

With regard to the provinces, we have received special reports from Bengal, Madras, and Bihar and Orissa.

BENGAL.

Major A. D. Stewart writes as follows:--

"In international relations and politics, narrow individualistic and selfish outlooks are being replaced gradually by a spirit of tolerance and co-operation. And this is happening not from sentimentality or by spread of any religious movement, but for the simple reason that it pays. Nations are finding more and more that

the prosperity of each is bound up in the general well-being of the community of nations, that all are mutually and intimately inter-dependent, and that disruption and war are foes to material progress and to the march of civilisation. So with hygiene, even in India the past year has illustrated these facts. The International Sanitary Convention of 1912 was in some ways a selfish measure designed mainly to benefit western nations from the inroads of infectious disease brought from eastern ports. The revised Sanitary Convention is laid down on broader principles and especially it allows that groups of nations geographically related may make conventions within the international one. Dr. Norman White's proposed convention for Far Eastern countries proposed that the port of departure of a vessel should be the basis on which ships arriving at any point should be dealt with. The revised International Convention adheres to the principle that the history of the ship during its voyage should be taken as the basis. Logically Dr. Norman White is correct, but practical commercial considerations favour the International Convention basis. The point is still under discussion. The establishment of the Epidemiological Bureau at Singapore has led to a quicker dissemination of news regarding infectious disease, while the monthly epidemiological survey of diseases has given a bird's-eye picture unobtainable before. The telegrams distributed by the Bureau have not proved of as great value as might have been anticipated in India, as the condition of the ship on arrival is still the determining factor in action. The Netherlands East Indies however consider conditions of ports of departure, and ships arriving from an infected port are put in quarantine conditions. The question of a Special International Convention for Far Eastern Countries would appropriately be discussed at the annual conference of the Far Eastern Association of Medicine which it is hoped will be held in Calcutta in 1927.

"The spirit of the times has been reflected in certain legislation in India during 1925. The International Labour Convention is an agreement of the League of Nations to which India is signatory, to mitigate conditions of labour amongst women and young persons. In India this has been given effect to in certain rules regarding the employment of young persons as lascars on board sea-going vessels, while the question of prohibiting female labour in mines has been considered. The fact that measures proposing to confer maternity benefits and to raise the age of consent were introduced into the Indian Legislative Assembly points to the direction of thought of a certain number of Indian politicians. There has been no great measure of legislation on public health subjects. The Public Health Commissioner with the Government of India is divorced from any real active interest in provincial sanitation and provincial Directors of Public Health learn more of sanitary happenings in other provinces from the newspapers than from any other source. Public health legislation as a whole needs careful revision. The need for a public health organisation in the rural areas especially is recognised by all. In Bengal, such a nucleus has been in existence for some time and is entirely a local one, appointed by and under the direct control of district boards. In other provinces as in Madras and the United Provinces, such a staff is partly at any rate provincialised. Which principle is correct is a matter for discussion, but all are agreed that the initiation of such a staff and its development are absolute necessities for the improvement of provincial public health. Bombay has passed a Food Adulteration Act and is framing rules for standards. Bengal probably does more practically in the matter of food adulteration, having an Act and rules of standards and three public analysts in the province. Most local Governments have Food Adulteration Acts but some yet lack facilities for their execution. The Calcutta Corporation has in its new Municipal Act been provided within ample means for coping with adulterated foods and drugs. Its Sub-Committee on Standards for Food has finished its deliberations and its report when published should be of assistance to many local bodies in

framing standards for Indian foodstuffs. In Bengal, a new Municipal Bill designed to extend the power of municipalities was referred on introduction by the Legislative Council, possibly for reasons not directly connected with the Bill. The water-supplies of Calcutta and Bombay are under extension: the latter city has decided to chlorinate its supply. In Madras city there has been considerable difficulty with the filtration of water owing to the production of sulphuretted hydrogen in the filter beds. The Corporation, however, apparently in opposition to the advice of various experts, have decided to continue and extend the present system of slow sand filtration.

"A feature of the year was the severe epidemic of small-pox in Calcutta and parts of Bengal. This outbreak was not unexpected, and followed close on the prediction at the end of 1924 that the increase of cases occurring then indicated an epidemic of severity in the coming spring of 1925. The districts benefited by advice more than Calcutta which suffered severely. The outbreak illustrated the fact that severe small-pox epidemics are apt to recur in India every six years, that the districts of Bengal were better prepared by re-vaccination than Calcutta, and that while on the whole infant vaccination was satisfactory, the greater part of the population are still unprotected by re-vaccination.

"The year 1925 saw a very distinct recrudescence of malaria in Bengal and the neighbouring provinces. The causes in Bengal would appear to have been a series of short monsoons culminating in a very deficient one in 1925. In Bengal the outbreaks would seem to have been a severe recrudescence of the ordinary endemic malaria and not specially due to any widespread malaria of 'pernicious' type.

"The Director of Public Health of Bengal has brought forward some evidence to show that there has been in several districts of Bengal a spread of kala-azar approaching in a few places almost epidemic intensity. Some but not all of these districts border on Assam districts. The endemicity of cholera in the deltaic areas of India, especially in the Gangetic delta has received considerable attention. It is particularly noteworthy that in 1924, the deltaic area of Bengal for the first time in the history of its cholera did not experience severe epidemic conditions, though most other districts of India commonly affected did so. The reasons are perhaps not all ascribable to local effort, but anti-cholera inoculation which has proved so effective in the Philippines and the Far East generally has been accepted by large numbers of the population in the Bengal districts.

"In the matter of sewage disposal, the appearance of the book by Mr. G. Bransby Williams (Chief Engineer, Bengal Public Health Department) on 'Sewage Disposal in the East' has focussed attention on this important problem. The book is noteworthy as advancing particularly the claims of sewage disposal on land even in deltaic areas. The disposal of the sewage of Calcutta and Bombay are difficult problems still awaiting solution."

MADRAS.

Major A. J. H. Russell writes as follows:—

"*Cholera*.—The problems connected with cholera have as in past years received greatest attention. The examination by statistical methods of cholera mortality figures over a long period of years has for long suggested itself as a method which might throw some light on the epidemiology of the disease, and the results obtained in 1924 by such an examination of the figures for Madras Presidency made it desirable to complete the investigation for all other Provinces of India. With help from the Indian Research Fund Association a mathematics graduate was employed, and two papers have already been published, whilst a third is ready to go to press. The two published papers deal with (1) periodicity in the incidence of cholera, and (2) the correlations between cholera on the one hand and climatic factors—rainfall, humidity, temperature and pres-

sure—on the other. These have been worked out for all Provinces of India except Bengal and Assam which will be dealt with separately in the third paper. During the past 30 years cholera seems to have passed over India in long waves with an interval of 6 years between the crests of the waves. The 72 month periodicity has been made evident by the use of Brownlee's method of periodogram analysis. While it is not maintained that there is any inherent permanency in such a periodic trend, yet it is of more than passing interest that this 72-month periodicity has existed all over the Indian continent for over 30 years. This fact may not be of great use in solving the many puzzling problems associated with individual outbreaks of the disease, but it has been of value in Madras in making a plan of campaign for fighting the disease. A confident forecast was made that during 1925 cholera would appear in epidemic form in the Presidency and unfortunately this prediction has proved to be only too true. The Southern Districts area has suffered, and is suffering, severely.

"At the instigation of the Public Health Commissioner with the Government of India, additional investigations in connection with cholera were undertaken. An officer of the Public Health Department is now engaged in carrying out a geographical survey of the Presidency as regards cholera. This necessitates a careful examination of all previous sanitary reports and Sanitary Commissioners' proceedings, as in these many relevant facts relating to cholera epidemics are to be found. Colonel King's reports especially are mines of information. A field investigation into the value of anti-cholera vaccine, and cholera bili-vaccine, and the value of different methods of treatment of cholera cases is also being carried out. A staff of six sub-assistant surgeons working under the direction of District Health Officers has been employed and details of their work are submitted weekly on special forms. It is hoped to collect sufficient statistics in more than one direction to make it worth while analysing the figures and make it possible to draw definite conclusions. The Indian Research Fund Association are financing the whole of this work. It is hoped to carry on similar investigations during 1926, provided the necessary funds are placed at my disposal.

"As regards correlation with weather factors, scores of correlation tables have already been set up and scores of correlation coefficients obtained, but the work is not yet complete. A large part, however, appears in the January 1926 number of the *Indian Journal of Medical Research* to which reference may be made, and it is hoped that 1926 will see this investigation brought to a close.

"*Malaria*.—A number of District Health Officers have made interesting reports on malaria in their districts, but they have as a rule far too much routine work to be able to devote time to special investigations in this direction. However, they do not have the training necessary for carrying out malarial surveys. Malaria is probably responsible for more deaths in Madras Presidency than cholera, small-pox, and plague added together, and the Government has been addressed regarding the importance of the question and the necessity for the appointment of a malariologist. The Malarial Unit attached to the King Institute has been kept constantly employed, by one Government department or another, e.g., Forest, and Public Works Department, but what is now wanted is a malarial bureau for the Presidency with a well trained malariologist in charge. So far, with one or two minor exceptions, no mosquito survey has been carried out in any part of the Presidency. It is not possible to suggest anti-malarial measures until that survey has been made.

"*Vaccination*.—The glycerine lymph now in use all over the Presidency continues to give excellent results. In 1924, over two million persons were vaccinated with a success rate of 94.6 per cent and 1925 will probably register a higher number of vaccination operations and at least on equal degree of success. When it is remembered that only 4 or 5 years ago the success rate was

as low as 59 per cent., the value of Colonel Cunningham's work in the King Institute will be appreciated. The rotary lancet which was adopted in 1924 has been found very satisfactory and vaccinators have appreciated its advantages.

"Teaching of Hygiene.—A visit to the Johns Hopkins School of Hygiene in America and to other schools in Great Britain made it evident that the teaching of hygiene in Madras left much to be desired. The Madras Government have been addressed on the subject, and it is probable that early in 1926 very considerable improvements will be effected, and the different branches included under the term hygiene will be dealt with by teachers especially qualified in these subjects. The two assistant-ships to the Professor of Hygiene which have previously been held by assistant surgeons from the Medical Department are now given to officers of the Public Health Department who have had practical experience in the districts. It is hoped to complete the re-organization of the Hygiene section of the Medical College on those lines during 1926.

"Typhoid fever.—In a number of districts investigation has shown that a very considerable number of 'fever' deaths are due to typhoid infections. In fact several medical officers have reported sharp epidemics of typhoid fever not only in the larger towns but in the smaller villages. The standard of sanitary knowledge being what it is, it is not surprising that these infections should be constantly met with, but they seem to be much more prevalent in some areas than in others, e.g., the West Coast districts of South Kanara and Malabar suffer severely. It is not difficult to suggest measures for combating these types of infection, when protected water supplies are so conspicuous by their absence, when flies breed everywhere and when food supplies are so constantly contaminated. The difficulty is to get one's recommendations carried out.

"Relapsing Fever.—The epidemic of relapsing fever has apparently died out in the plains districts, as no cases have been reported for several months. The infection, however, continues to appear here and there in the Nilgiris and Annamalai Hills among the hill tribes and estate coolies, so that the danger is by no means past. The researches conducted by Col. Cunningham at the King Institute into the spirochetes of relapsing fever and their serological reactions were published in a paper read by Col. Cunningham before the Royal Society of Tropical Medicine and Hygiene in September.

"Hook-worm work.—The Rockefeller Foundation continued their hook-worm campaign in this Presidency during the year. During the absence on furlough of Dr. Kendrick, M.B., of the Rockefeller Foundation, an Indian member of the Madras Public Health Department carried on the work. Surveys have been completed in several districts and the incidence of hook-worm infection is now fairly accurately known for different areas of Madras. In the Ceded Districts the percentage of infection may be as low as 5 to 12 per cent., whilst in several of the wet districts such as those on the West Coast approximately 100 per cent. of the people are infected. The time is now ripe for a further step forward in the campaign. Soil contamination cannot be prevented until the rural population realise the danger of promiscuous defecation and begin to make use of private and public latrines, and unless Government and local bodies can do something shortly in the direction of providing latrines in unions and villages, the Rockefeller Foundation may feel that their expenditure in Madras is not being justified. It would be entirely regrettable if they were to withdraw their co-operation now.

"It is hoped that one or two of the District Health Officers in the Presidency will be awarded Rockefeller Scholarships during the coming year, as it is felt that the wider training they will obtain during the period of study leave in America or Britain will be all to the advantage of the Presidency Health Service. Men with special knowledge of vital statistics and epidemiology are moreover urgently required and those who obtain

scholarships will be expected to specialize in one or other of these branches.

"No addition to the Public Health staffs has been made during 1925, but with the partial remission of the provincial contribution to the Government of India, it is hoped that funds will be available to permit of one or two of the developments which have been already laid before Government for sanction. It is impossible, for example, for a single Health Inspector to control to any effective degree public health activities in a taluk which may be 1,000 square miles in extent. The people are beginning to recognize the value of a trained health staff and as their services are more and more in demand a larger number of Health Inspectors are required. This is only one of the directions in which expansion of the Public Health Department is desirable."

BIHAR AND ORISSA.

Lieutenant-Colonel W. C. Ross contributes the following notes:—

"In January 1925, the second paper by Lieutenant-Colonel W. C. Ross, and Dr. K. N. Bagchi on 'The Seasonal variation in the Reaction and hardness of river water in India' was published in the *Indian Journal of Medical Research*. This completed an investigation into the chemistry of river waters which took more than three years to carry out and which has determined the conditions governing the use of alum, alumino-ferric, etc., in the sedimentation and filtration of water supplies and has worked out the nature and causes of the seasonal variation and reaction in river waters, which was previously unknown and which was the real factor causing all the difficulties in filtration.

"Cholera.—The use of kaolin as a routine treatment for cholera was first introduced in Bihar by Dr. Thompson in the Jharia Coal field. Profiting by his experience, I introduced it on a large scale during the severe cholera epidemic of 1924; and my experience is that kaolin is a very effective remedy when it is promptly used in the early stages of the disease. It has very little value in the later stages.

"I found that kaolin treatment more than halved the death rate, reducing it to between 10 and 20 per cent. according to the circumstances under which it was used, as compared with a mortality which is nearly always over 50 per cent. in untreated cases, and seldom below 30 per cent. with ordinary treatment, such as camphor, opium, essential oils, etc.

"I consider that kaolin is most suitable for general use amongst an ignorant population, as it is not poisonous and can be safely given by anyone with nothing more than the necessary instructions to guide him. Further, kaolin is chemically stable, does not decompose, nor deteriorate and it is cheap and can safely be entrusted to police officers, school masters, patwaris, and other non-medical officials in rural areas.

"The prevalence of epidemic diseases in Bihar and Orissa during 1925 has not been severe. Cholera was epidemic in the district of Purnea and was somewhat prevalent in Orissa and the Patna Divisions. But there was no widespread or severe epidemic.

"The incidence of plague is gradually declining; and malaria although epidemic in Puri and Cuttack has been less prevalent in other parts of the province. The incidence of small-pox during the year increased considerably, but did not attain to epidemic dimensions. The year has therefore been on the whole a healthy one.

"Municipal Sanitation.—The sanitation of municipalities in the province is slowly but surely deteriorating and is likely to culminate in severe epidemics of cholera, plague and enteric fever in many of the towns of the province, unless the administration is made more effective and more efficient. During October there has been a severe epidemic of cholera in Bhagalpur town which is a concrete example of what may be expected throughout the province under existing conditions.

"Health Department.—During the year many districts have put forward schemes for a public health staff organisation, and the schemes have been actually started

in the districts of Darbhanga, Muzaffarpur, Cuttack, Manbhum, and Balasore and are pending in Saran, Patna, Bhagalpur and other districts.

"Reorganisation of the Public Health Department of the province has been arranged during the year and will be introduced early next year. A separate cadre is being provided for the Public Health Department and permanent provision is being made for five School Medical Officers, five Assistant School Medical Officers and ten Epidemic Doctors, who will be employed on epidemic duty when required and will carry out propaganda and investigation work at other times.

"New Public Health Laboratories with ample accommodation and equipment have been provided at Patna during the year, and afforded facilities both for the routine work of chemical analysis of foods and water supplies and for bacteriological investigation work.

"*Vaccination.*—The refrigeration plant at Namkum Vaccine Depot has been duplicated and glycerinated vaccine lymph is now prepared in large quantities and kept in cold storage one year before issue. This Depot is probably the largest one in India and has a maximum output of five million doses of vaccine per annum. The amount issued annually is over three million doses, and a reserve of over two million doses is always kept in stock."

Colonel Ross also notes that there has been a large demand, not only in Bihar and Orissa, but from all over India for the publications of the provincial Public Health Department issued in 1924. These have been reprinted in 1925, and with his letter are enclosed copies of three very useful and simple pamphlets, which we hope to review at a later date. These are a *Mea Manual for Bihar and Orissa*, a pamphlet entitled *Simple instructions for the Prevention of Epidemic Diseases*, and a *Syllabus of Lectures in Hygiene* for school medical officers.

GENERAL.

Dr. J. W. Tomb describes the *public health organisation* in the Asansol Mines' Board of Health area, with its population of some 329,363 souls. The chief epidemic diseases in the settlement are cholera and small-pox. The unit of sanitary administration in the area is the Sanitary Assistant with a circle some 36 square miles in area. There are 13 of such assistants whose duty it is to collect and check vital statistics, verify vital occurrences, submit a weekly report, take immediate steps on the appearance of any epidemic disease, carry out vaccinations, and carry on propaganda work. A system of coloured cards is in vogue for the uneducated *chowkidars*, and a reward of Re. 1 is paid for each case of cholera or small-pox notified. The card has to be delivered by the *chowkidar* to the Sanitary Assistant, or if he is out, placed in a box with a glass front so that it is seen immediately the latter returns home. In connection with small-pox it is hopeless under Indian conditions to attempt the segregation of the patient in his home; a better practice is to vaccinate all contacts immediately. In cholera the essential oils' mixture is freely and widely used. In addition to taking immediate local measures, the Sanitary Assistant must also immediately report the occurrence of the epidemic to headquarters. Epidemics in collieries are dealt with by Sanitary Inspectors on lines similar to those for Sanitary Assistants in rural areas. A special staff of six promoted Sanitary Assistants who have been especially trained in malaria is maintained, also three midwives, and a sub-assistant surgeon for medical inspection of schools. The entire cost of the department under a District Health Officer works out as Rs. 66,220 per annum, or considerably less than one anna per head per annum of the population concerned. At one time this area was a hot-bed of disease, to-day its death rates from cholera, small-pox, intestinal and respiratory diseases are very much lower than those for Calcutta, Howrah and Dacca.

The immense problem of *medical relief for the rural areas* of India has aroused much comment during the

year, and was the subject of our editorial for last May. A very interesting address on the same subject was also given by Major Chopra in Calcutta during the year. This problem is an age-old one, and it will not be solved in a day. It may be true that present-day modern scientific medicine still only reaches one-tenth of the population of India; but what it *does* reach it influences profoundly, as witness the extensive kala-azar survey work and staff's activities in Assam. There are advocates of different so-called solutions of this problem. One authority will urge the extension of medical schools in the *mofussil* and of hospitals and dispensaries, "India is too poor to afford any but really good doctors,"—but such widespread extension is prohibitively expensive. A second school of thought advocates the subsidy by Government of Ayurvedic practitioners in the *mofussil*, to give them a smattering of "western" medicine and place them on an official state register. The writer—at least—can see no point in such a suggestion; if indigenous and Ayurvedic medicine is worth subsidising, its exponents have only got to prove to the general public the value of their methods, and wealthy Indians interested will no doubt come forward to subsidise hospitals and dispensaries run on Ayurvedic lines. A third school of opinion counsels the creation of large numbers of low-grade practitioners of the former "hospital assistant" class, partly subsidised by Government, sent out as missionaries more or less into the *mofussil* areas, and there left to earn a livelihood out of the subsidy plus their own efforts.

The matter is far too vast and too vitally important to deal with within the limits of this review, and for several years it has received the closest attention of the Imperial and Provincial Governments. In reality, huge as the problem is, it is but part of a still more immense problem,—that of the creation of a "public health conscience" in the general population of India. Such a happy solution may appear to be as far distant as the Greek calends, but it is perhaps not so impossible as at first sight it would appear to be. British public health legislation of to-day is the creation of almost less than a century of effort, and a hundred years ago the British public with regard to public health matters was where the Indian public is to-day. In Assam the unceasing work of the kala-azar survey staff has almost created such a "conscience" and there is actually popular support for the work of this staff; elsewhere in India—especially in the plague infected provinces—public opinion within the past 15 years has veered round from almost fanatical opposition to almost cordial support. *Educate, educate, educate*, and the problem may solve itself. At both ends of the scale education is wanted; at one end the creation by post-graduate teaching of the highest possible order of teachers of medicine in the India of to-morrow, so that they will be the equals of any in Europe; at the other, the teaching of the rudiments of personal and public hygiene in an attractive method in primary and secondary schools and colleges throughout India. In two generations of such effort a veritable revolution might be accomplished; indeed much in both directions is already being done.

The importance of the cinema in such work is perhaps overlooked to some extent. One has only to attend any cinema performance in Calcutta or Bombay to see how the Indian masses flock to such performances, to cheer the heroine and hiss the villain. *Panem et circenses* is still the quickest road to popularity in India, as elsewhere. In place of giving such audiences "close-ups" of erotic love dramas and of the activities of cat burglars and other friends of the police, why not at times give them educational films on public health problems, as studied from an Indian and national point of view?

The work in the *mofussil* districts of India of the innumerable mission hospitals deserves nothing but unstinted praise alike from European and Indian, from the interested outside British medico and from the Indian patient. As far as the writer knows—and he has for years at a stretch been in close contact with medical

mission hospitals in India—there is here no disharmony; rather a unique spirit of good-will and progress.

In our issue for last August, Lieutenant-Colonel W. C. Ross comments on the need for a declared *public health policy* for India. Even in Europe preventive medicine—the ideal of the future in which disease will not merely be treated but prevented from occurring—is still in embryo. There are here with regard to India four essential elements. The first is to know the facts; how the different epidemic diseases of India spread and how to prevent them. To a considerable extent we already possess this knowledge. The second is to provide funds, and here organisation is of prime importance. Given accurate knowledge a small sum may be expended on much more useful measures than a much larger sum squandered on measures based upon ignorance. It is in this connection especially that trained epidemiological units are of value. A Finance Department, keen upon retrenchment, may consider that such epidemiological units can be created when the emergency arises. They cannot; unless they are there, trained beforehand and available on the spot, their services will be inefficient. The third essential is organisation and co-ordination, and here a policy of decentralisation with a headquarters for co-ordination and direction of effort is needed; to utilise what money is available to the best advantage. The public health staff needs to be mobile, to be whole-time and to be independent of private medical practice for part of its livelihood. The fourth essential is to arrange between the different departments concerned as to how to procure what is wanted; a strong central organisation, a policy of decentralisation in actual execution, though not freed from responsibility to the central organisation,—and most important of all sufficient funds with which to fight epidemic and preventable disease.

A very striking address during the year was that by Dr. Andrew Balfour, Director of the new London School of Hygiene and Tropical Medicine, on the trend of modern hygiene, published in the *Lancet* for the 9th May 1925, and reviewed in our columns for last October on p. 493; considerations of space here prevent our doing more than merely refer to it.

WATER-SUPPLIES.

Several important papers have appeared during the year. Lieutenant-Colonel W. C. Ross and K. N. Bagchi continue and conclude their studies of the seasonal variation in reaction and hardness of Indian water-supplies with studies of the Ganges and Sone rivers. In April to July the calcium nitrate content shows a great increase, atmospheric conditions in India being extra favourable to the development of free nitric acid during the rains. It is this fact which explains the continuous fertility of the Gaugetic plain, despite its continuous cultivation and inadequate manuring; over $2\frac{1}{2}$ tons of nitric acid are precipitated over each square mile on it per annum.

Major A. D. Stewart and Rao Sahib V. G. Raju deal with the economical use of alum in mechanical filters. Rapid sand filters, when filtering waters which are not turbid but have had some sort of storage previously, reach their maximal filtering efficiency after being fed with coagulated water for an hour only, and the use of alum can thereafter be altogether dispensed with, without in any way impairing that efficiency. A considerable reduction in the expenditure of alum can thus be effected. The second author has also studied the working of slow sand filters in India. At the Hooghly Chinsura waterworks, during June, July and August the results are much inferior to those in other months, and there is a marked increase in non-lactose fermentors. At the Calcutta waterworks the results are even worse. The probable cause of this break-down in efficiency is the deposit of silt as a result of the monsoon flooding of the Hooghly. He suggests that no lactose fermentors in 10 c.c. should be adopted as a satisfactory standard for slow sand filters under Indian conditions. Improvements may be effected by (a) chlorinating the water for the first day or two after periodical scraping

of the top of the sand surface; (b) chlorinating the replenished fresh sand bed at the time of renewal by passing through it for a few hours water containing a slight excess of chlorine; (c) abolition of the arbitrary limits set for loss of head; (d) the chlorination of unfiltered water to suppress algal growth; (e) improvement in the method of storage of raw water. The best method of chlorinating is to combine the alum and bleaching powder in one tank and run the combined solution into the raw water as it falls into the settling tank.

Major H. H. King comments on the stability of solid calcium hypochlorite, with special reference to its use in chlorinating water-supplies and in preparing surgical lotions. Ordinary "bleach" is very unstable under tropical conditions. Stabilised bleach—prepared by the addition of lime—is far more stable; a very dry powder of calcium hypochlorite, dried *in vacuo*, and kept in airtight tins with a washer round the lid, painted with bituminous paint in order to prevent rust, was also found to be very stable. The latter gives very little sediment on solution. He concludes that solid calcium hypochlorite in suitable containers is the most important of disinfectants to be carried with armies on campaigns or during manœuvres.

From the King Institute of Preventive Medicine, Madras, Dr. Turkhud writes:—

"The systematic periodical examinations of protected water-supplies in the Presidency (municipalities, jails, and railway stations), continued and wherever defects were noticed remedial measures were suggested, thereby enabling the authorities responsible for the maintenance of the supplies to keep them in proper order.

"The Madras City water-supply question, which was still pending, in spite of the specific recommendations made by the Committee on Water Filtration, and supported by Lieutenant-Colonel W. W. Clemesha (ret'd.), was again referred to the Director of the King Institute by the Government of Madras. A detailed analysis of samples of water drawn from several representative points of the city water-supply system was conducted and the conclusion reached was that the methods at present in vogue are totally inadequate and that rapid filtration should be resorted to in order to render the water potable.

"As the Corporation of Madras had expressed their disapproval of this system, on the score of expense and of the doubtful improvement that will follow its introduction, it was suggested by the Director, King Institute, that the 3 million gallons of raw water chlorinated imperfectly and mixed with the slow sand filtered supply, should be filtered through rapid filters. Government, accepting this suggestion, have directed that this be carried into effect. They have at the same time turned down the proposal of the Corporation to construct more slow sand filters.

"Research into the best and most economical means of water purification which has been carried out for over 12 years at the experimental filter installation at the King Institute, was continued and the method of filtering slow sand filters with an initial but small dose of alum was found to be a complete success. The method was applied in actual waterworks practice in two municipal supplies with very satisfactory results. Experiments on percolating filters are now in progress. Government have now ordered the retention of the experimental filter installation on a permanent basis.

"The bacteriology of water-supplies continued to be the subject of special study by Mr. T. N. S. Raghavachari during the year. The lactose fermenters found in several samples of the soil, animal faeces, milk and water were examined with reference to their fermentative and other biochemical reactions. The results obtained by him resemble those of the American bacteriologists, except in certain minor details.

"Mr. Raghavachari has also been engaged in the application of the citrate utilization test of Koser to the lactose fermenters isolated from water-supplies in this Presidency. He reports that this test marks a

distinct step forward in the classification of lactose fermenters, in that by this test the truly faecal can be sharply separated out from those that are derived from non-faecal sources.

"A systematic investigation into a very interesting case of a deep well supply becoming unfit for drinking purposes as a result of manganese troubles, with the consequent necessity for finding another suitable source of supply for an emigrant population, was undertaken by Dr. Turkhud and Mr. Raghavachari. A deep bore-hole about 300 yards away from the well revealed the presence of phenomenally high figures for free ammonia, besides containing manganese in solution. The occurrence of manganese in water-supplies has not been recorded hitherto in this Presidency. The possibility of troublesome growths occurring in the pipe line when a water containing manganese and excess of organic matter was passed through it necessitated the institution of experiments for demanganising the water. These are in progress and so far as they go are promising of good results."

FOOD SUPPLIES.

Mr. Hawley, Public Analyst with the Government of Madras, completed an extensive analytical study of standards suitable for adoption in that Presidency for milk and butter supplies, and his recommendations were submitted to Government. In the *Indian Medical Record* S. N. De comments on the serious question of infected ice cream in India. The methylene blue reduction test was applied to a large number of samples taken from various sources in Calcutta. If the methylene blue solution be decolourised in 20 minutes it means that the ice cream contains 20 million or more bacteria per c.c. Further evidence as to contamination can be obtained by culturing for faecal bacteria. The milk may be severely contaminated although without odour. All samples of *kulpi baraf* which give a positive methylene blue reaction should be rejected; on the other hand it does not follow that a negative reaction always means that the ice cream is wholesome.

RABIES.

This disease may perhaps be most suitably considered under this section. Lieutenant E. C. R. Fox, I.M.D., Superintendent of the Bengal Pasteur Institute, writes as follows:—

"Two papers were published during the year, both by Lieutenant-Colonel J. W. Cornwall, in the *Indian Journal of Medical Research*. The first deals with the estimation of the blood-sugar in normal rabbits and in rabbits inoculated intracranially with rabies fixed virus. It was shewn that the blood-sugar rises slightly after inoculation; drops a little about the 4th day, and on the 6th and 7th days there is marked hyperglycaemia. The second paper deals with Negri bodies. The author feels assured that the majority of these bodies and the corpuscles seen in the large nerve cells are the expression of the intracellular growth of the specific organism of rabies. Spores of the organism in the nerve cells mature, ripen and burst, and the contained corpuscles emerge into the cell protoplasm.

"Reports published during the year shew a general increase in the number of patients seeking treatment at antirabic centres. Two new such centres were opened during the year, one at Nagpur, and one at Lahore. The Kasauli Institute in 1924 treated 7,852 patients, this being the highest number on record. The Director remarks—"The fact of such an increase being possible tends to show the existence of a large untreated population at risk from rabid—or supposedly rabid—animal bites. . . . It is possible that opening of local centres would better tap such a population and so extend the benefits of antirabic treatment."

"Experiments are being carried on in Kasauli and Rangoon as to the effect of heat on the potency of antirabic vaccine. The results have not yet been published."

MISCELLANEA.

The medical examination of school children is now an important part of the public health programme of all the provinces of India. J. N. Maitra records the results of examination of students at the Presidency College, Calcutta. The results are bad, to say the least of it; on the whole 80 per cent. of students were found to be defective physically in one or other respect. Only 6 per cent shewed good muscular development; 37 per cent stooped; 39 per cent. had defective vision; 24 per cent shewed defective or carious teeth.

From Bombay, Dr. S. N. Goré records the results of investigations into fumigation by calcium cyanide. Its use for the generation of HCN gas is both simpler and more convenient than the use of sulphuric acid with sodium or potassium cyanide. Mere exposure of calcium cyanide to air results in evolution of most of its HCN gas in 1½ hours. One oz. of calcium cyanide per 100 c. ft. gives a lethal concentration in air-tight spaces, attained in 1½ hours and maintained for about 4 hours. When used in the open, however, a lethal concentration is not obtained. Diffusion of HCN gas from calcium cyanide in narrow channels, dug in the ground, is too poor to be effective.

Major A. D. Stewart and N. L. Bannerjee describe the commercial preparation of a neutral soft soap, cheap and practically inodorous, from fish oil by running the oil into an excess of KOH lye gradually, and diluting, boiling the mixture, and subsequently blowing air through it. Excess of alkali in the soap can be easily neutralised by adding a 28 per cent. solution of ammonium chloride in excess of the theoretical amount.

SEWAGE DISPOSAL.

Dr. Turkhud writes:—

"The Committee on water purification was ordered by Government to carry out experiments on the problem of sewage disposal. The necessary staff having been provided, experiments have already been projected. The sewage disposal plant on which the first set of experiments has been undertaken consists of septic and Imhoff tanks, percolating and contact beds. Other types of plants in the city of Madras will also be taken up as soon as possible. This enquiry, which is perhaps the first systematic one of its kind in this country, should yield a considerable amount of useful material of great help to sanitations.

"Testing of disinfectants.—The time-honoured Rideal Walker test for the determination of carbolic coefficients of disinfectants was found in this Institute to yield invariably much lower figures than those claimed by the manufacturers on the strength of tests carried out in English laboratories. Last year, the local agents of a well-known brand of disinfectant, acting on the advice of their principals in England, submitted a sample of their product. Our tests yielded a figure which was far below that by the English laboratory test. The manufacturers ventured to suggest in a lengthy communication to the Director, King Institute, Guindy, several reasons for the low figures given, among which it was stated the Rideal Walker test has been practically superseded in England by the British Admiralty test and that in the latter test considerable importance was attached to the use of particular strains of *B. typhosus*. A detailed investigation into the merits of these suggestions was undertaken and numerous tests have been carried out by Messrs. T. N. S. Raghavachari and P. V. Sitaram, acting in collaboration with Mr. Hawley, the Public Analyst.

"The conclusions arrived at point to the following facts:—

- (i) The British Admiralty test, which furnishes conditions similar to those occurring in nature, yields a lower figure than the standard Rideal Walker test.
- (ii) The Rideal Walker test yields figures which are generally about 50 per cent less than those claimed by the manufacturers.

Hopkins, Rawling and Chapman do not appear to accept the results of either the Rideal Walker or British

Admiralty test. The King Institute strain does not therefore account in any way for the low figures obtained. From a published paper issued by the Royal Institute of Public Health, London, it is found that the same samples of disinfectants sent out to various laboratories in the world, have yielded results which vary within the wide limits of 114 to 183 per cent."

OBSTETRICS, GYNÆCOLOGY, INFANT WELFARE.

Despite the lengthy review of recent progress in these subjects in our issue for last month by Major V. B. Green-Armytage, a number of papers published during the year by workers in India call for review.

Priority of place must certainly be given to the paper by Miss G. Stapleton, M.B., W.M.S., published in our December issue, on *pelvic measurements in Indian women*. These measurements were determined on 200 Indian women at the Dufferin Hospital, Agra, at the 8th to 10th day after delivery. She concludes as follows:—

"1. The average external pelvic measurements of Indian women in the Agra district, excluding those with abnormally small pelvis, are:—

(a) Inter-spinal diameter, 8½"; inter-cristal under 9½"; external conjugate, 7½".

(b) The diagonal-conjugate is on the average 4½".

(c) The average weight of the babies at birth was 6 lbs.

(d) Slight grades of flat pelvis are found apart from and history of osteomalacia or rickets."

The same author contributes a striking analysis of 72 cases of late rickets and osteomalacia seen at the Lady Hardinge Hospital, Delhi, during the period 1921-24. Eighty per cent of these were associated with *purdah* life. There is no sharp dividing line between late rickets and osteomalacia, and intermediate cases are seen with characteristic symptoms of both diseases. The difference in symptomatology of the two diseases appears to be due to conditions in the tissues, largely dependent upon the age of the patient. The determining causes in the majority of patients are the *purdah* system, i.e., absence of sunlight, of fresh air, and of exercise. The diseases usually commence about puberty or in early adult life. Osteomalacia is not uncommon in young Indian women, quite apart from pregnancy. Tetany frequently occurs in the course of osteomalacia, and this suggests some close relationship between the metabolic disturbances that give rise to tetany and to osteomalacia respectively. These conclusions, based upon the observations of patients at Delhi, closely agree with those for patients seen at Nasik by Dr. Stapleton and the late Major Hutchinson.

Lieutenant-Colonel C. C. Murison comments on the midwife in Indian practice. The common Indian *dhai* is responsible for a revolting septic technique and appalling maternal and infantile mortality. The increase of special maternity hospitals in India has been slow; at Belgaum civil hospital accommodation was steadily extended, and the number of such cases rose from 8 in 1910 to 131 in 1924. He suggests compulsory registration of all *dhais*, making them attend compulsorily an elementary course of instruction at hospital of a month or more; registering them, and appointing them to *mofussil* hospitals and dispensaries.

An investigation into the bacteriology of *puerperal fever* was conducted by the workers at the King Institute, Guindy, Madras, at the Government Maternity Hospital, Madras, during the year. Many of these cases had followed instrumental delivery. Out of a total of 88 patients bacteriologically examined, streptococci were detected in the vagina of 36, and in the uterine cavity in 29 patients. Of the 36 strains isolated from the vagina, 29 were hæmolytic, and 7 non-hæmolytic. Of the 29 strains from the uterus 27 were hæmolytic. It is hoped that the results of this investigation will be

published in due course. *Streptococcus subacidus* appears to be the prevalent type (adopting Holman's method of differentiation and classification).

B. B. Bhattacharya describes the histo-pathology of eclampsia in an illustrated article. Liver sections from fatal cases shew periportal necrosis and hæmorrhage. Other sections from cases of the pernicious vomiting of pregnancy shew central necrosis of the lobules. He dwells upon the great need for ante-natal clinics in India.

Of general obstetric cases, a number have been recorded of special interest in different journals. D. Pereira advocates calcium lactate administered during pregnancy to prevent still-births. Dr. H. G. Roberts of Shillong records a case of post-mortem Cæsarian section; the mother who was suffering from eclampsia died on the operation table before operation was commenced, but a live fœtus was delivered and survived. Lieutenant-Colonel P. S. Mills records an extraordinary case of extra-uterine gestation in the left Fallopian tube and broad ligament, going on to full term. At laparotomy a living child was delivered and the mother made an un-interrupted recovery. She was a *gwalla* by caste, aged 20, and in her first pregnancy. The fœtal sac was free from adhesions, and the placental site lay almost wholly within the tube. The operation was thus straightforward. R. N. Kundu records a case of spontaneous inversion of the uterus following delivery and precipitate labour. The patient was found sitting on the floor and bleeding profusely. The inverted uterus was replaced by pressure with the hand covered with a gauze pad. Hot intrauterine douches were given, injections of ergot, and 20 c.c. of anti-streptococcal serum. The patient recovered.

S. Serlachar records a case of what was apparently pulmonary embolism following the administration intravenously of 1 c.c. of pituitrin on the 7th day of the puerperium, apparently due to dislodging of clot and embolus formation. Y. S. Row comments on such cases; the intravenous use of pituitrin causes a sudden rise of blood pressure, constriction of the coronary arteries and a slow heart beat. If pituitrin is to be given intravenously at all—and not hypodermically—it should be given well diluted with normal or hypertonic saline solution.

Gynæcological Cases.—Several such individual cases deserve mention. Cases of large or enormous ovarian tumours are recorded by S. C. Das Gupta, who records two cases; by Rai Sahib C. Nath who records ovariotomy on a tumour weighing 24½ lbs.; and by B. S. Rao. The last mentioned author records a case of large ovarian tumour which developed during pregnancy. Labour was normal and ovariotomy was performed a month later; 1½ bucketfuls of fluid were withdrawn from the ovarian cyst before its removal. I. B. Basu records a case of malignant tumour of the ovary together with pregnancy in a Nepalese girl aged 15, with marked œdema and ascites. Operation shewed a malignant tumour of the right ovary the size of a football. After removal of the tumour labour ensued at the eighth month of pregnancy, two months after the ovariotomy. The child was still-born, and the mother died 48 hours later with ascites, œdema of the subcutaneous tissues and œdema of the lungs.

J. M. Das describes a case of congenital absence of the vagina in a Hindu girl of 16, accompanied by bilateral hæmatosalpinx.

Infant Feeding.—Major E. H. Vere Hodge draws attention to some points in artificial feeding. "Take a child off the breast prematurely, and his troubles begin." The normal acid barrier of the stomach may be interfered with and most artificial foods contain too little lecithin. Purchased milk in India is quite unsuitable, and a private cow should be kept; it must be healthy and fed upon fresh as well as upon dried fodder. Cows in the plains are not satisfactory during the hot weather. The newly introduced desiccated cow's milk may be a possible substitute. It contains vitamins A and B in sufficient quantity, but C is absent, and cod-liver oil, fruit juice,

or P. D. & Co.'s "Metagen" should be used to supplement it. Dried milk is often better and more wholesome than milk from an inefficient cow in the plains of India during the hot weather; whilst proprietary foods are more often misused than not.

Major V. B. Green-Armytage considers drugs almost useless in infantile diarrhoea. The mother's nipples should be cleansed carefully before and after each feed, and three-hourly feeds given, each of seven minutes' duration. Five grains of sodium bicarbonate should be given in 1 oz. of water before each feed. The mother must avoid constipation and drink a tumblerful of water before each feed. Hot and cold sponging and massage of the breasts should be carried out, and the infant weighed daily. Warm enemata are the best line of treatment for an infant passing grey, slimy stools; 2 to 5 minims of tincture camphore co. for green lenteria. If the mother cannot feed the child, cow's or goat's milk should be given, but in the vast majority of cases it is a mistake to take the infant off the breast. Patent foods he condemns absolutely.

Child Welfare.—In a very striking address, published in the *Indian Medical Record* for last March, Dr. P. Ganguli outlines "our duty towards the future generation in India." Puerperal tetanus is so common in Bengal that it is attributed to the visitation of a ghost—the *pencha*. It is estimated that 30,000 infants a year die from this preventable disease in Bengal, out of a general child mortality of some 250,000 a year, again most of it preventable. After tetanus come diarrhoea and dysentery as great causes of infantile deaths. The author writes:—"There should be no winking at some perilous customs prevalent amongst the Hindus...untouchability of the mother for two to three weeks after confinement, the selection of the worst, damp, ill-ventilated and dark room of the house for confinement, the use of old dirty beddings." Maternity and child-welfare are immensely urgent problems in India; in England during the war women of the highest and noblest rank were content to enter hospitals for the wounded and to carry out the meanest of tasks; in India it is almost impossible to get Hindu or Mahomedan girls of any status at all to train as nurses. Maternity homes should be started in every centre of population in the land, and be run by subsidised trained Indian nurses; only in some such way can maternity-welfare become a reality in India, and not merely a pious hope. Further, the milk supply is becoming a most urgent problem all over India. The cattle of Bengal, at least, are undernourished, their fodder deficient in vitamins, their milk yield miserably poor. Further, in a Bengali household the young mother is the most neglected member of the family and what milk is available is taken by the male members of the household. "We Bengalis are a dying race...In ignorance of the first principles of health, we delegate our womenfolk to an inferior status in the household. The barbarous custom practised in the name of religion which makes mothers untouchable for 2 to 3 weeks after confinement, colossal ignorance of the first principles of the dietary of children, neglect of the mother after delivery, all these are contributory factors. Yet rich people will hesitate to spend Rs. 20 or Rs. 30 on a confinement, who will not hesitate to spend Rs. 1,000 on celebrating the *annaprasna* ceremony of the child." Finally it is up to the young Indian doctor to preach in season and out of season the need for proper maternity and child-welfare.

The same lessons are taught in a similar article by Ashutosh Roy of Hazaribagh, a well known senior Indian physician; and in still other articles. In the meantime the success of Baby Week all over India shews that the matter has at last aroused interest.

OPHTHALMOLOGY.

The following review for the year is very kindly contributed by Major R. E. Wright of Madras:—

"The Convention of English-Speaking Ophthalmologists was held in London in the month of July. It had

not been found possible to arrange an international gathering. The last congress was held in London in 1872. It was intended to hold an international congress in 1914, but war broke out. The Minister of Health drew attention to the fact that ophthalmic service, restricted to the well-to-do 50 years ago, was now within the reach of all. It was particularly organised for children, and in England there were 500 medical men and 482 clinics specially for this purpose, and a further extension was provided by ophthalmic benefits under the National Health Insurance.

"Sir J. Parsons delivered the Bowman lecture on 'The foundation of vision' and ended on a note that should be carefully weighed by all Indian ophthalmologists. He says 'future advances' (in ophthalmology) 'will not depend, as heretofore, on refinements of operative technique, but will rather depend on and be revolutionised by an increased knowledge of the bio-chemistry of the eye and the physiology of vision.' It is well to remember that we, Indian ophthalmologists, are often regarded in the outside world as 'cataract punchers' and we should try to act on his forecast.

"Indian literature has not been very rich in papers dealing with ophthalmological subjects in the past year and does not reflect the actual amount of work going on. Certain subjects have been published by Indian eye workers in ophthalmic journals, whilst visitors to the east and the overseas tours of our own ophthalmologists have brought current work in this country before the profession. Dr. H. T. Holland gave his views on important aspects of cataract work to several American meetings.

"Major Acton's work on epidemic dropsy is of interest in India where glaucoma is so prevalent. The association of a definite type of glaucoma with epidemic dropsy has been established by Maynard (1909) and Coppinger. The correlation suggests that it is determined by the same factors. Acton considers that epidemic dropsy 'is a toxic syndrome caused by the ingestion of poisonous bases formed in rice under certain conditions, although similar poisons can be formed in other foods under storage.'

"The operative treatment of cataract as usual, received a large share of attention (almost an unfair share, as cataract is by no means the most important cause of our preventable blindness).

"Capt. M. M. Cruickshank publishes details of 115 cases of phacocresis, and touches on the after effects on the vitreous of removing the capsule. These he does not regard as of very great import. Concerning recent changes in the vitreous he confines himself to fine threads or fibres in the pupil and fine dust-like pigmentary deposits seen with the loupe. Such changes in his series were less prevalent than in eyes operated on by other methods (presumably intra-capsular). He refers to the difficulty of interpreting changes in the anterior layers of the vitreous or hyaloid membrane with relation to the influence of trauma. Experienced slit lamp workers would agree with this provided the changes are within the limits dealt with by Cruickshank; but certain abnormal post-operative opacities are easily differentiated from the various normal varieties. In the writer's opinion neither the loupe nor the corneal microscope is the most practical way of determining vitreous opacities of the variety that the patient is concerned with but rather a good type electric ophthalmoscope. The origin of non-cellular vitreous opacities including the streamers seen after vitreous escapes, is a difficult study and should be checked in the laboratory. There seems to be a confusion of ideas where the author speaks of the cells of the posterior capsule, and some of the references are difficult of verification. The remainder of the paper analyses a good series of 115 apparently unselected phacocresis cases. The apparatus used is noteworthy in affording varying pressures and portability, without requiring electricity. The iris prolapse rate of 3 in 100 is average good. To Barraquer is attributed an iris prolapse rate of 0.4 per cent.

attained by adopting peripheral iridectomy and suturing the section. This figure is difficult for us to understand in India and must be the envy of all operators with large experience. The author regards iris prolapse as the worst of complications and considers 'speed' in technique pre-eminently to blame. It is doubtful whether this opinion would meet with general acceptance. Most of the 'big' operators in India have varied enormously in speed and knife movements, yet there does not appear to be a vast difference in their iris prolapse rate. The tumbling of the lens and the conducting of the final stages of delivery so that the iris is not disturbed from the hyaloid membrane, referred to by the author, may largely explain Barraquer's prolapse rate.

"The same author contributes an article on 'Choroidal hemorrhage following cataract extraction', which includes notes on other sequelae such as the drawn-up or boat-shaped pupil and striate keratitis. Working in Holland's clinic, where, he remarks, the incidence of glaucoma is very high, he collected 30 cases of choroidal hemorrhage in 2,777 extractions. Holland advises extraction with capsulotomy where the tonometer registers more than 42 mm. of Hg. (McLean). This is certainly a careful figure, the normal for McLean's instrument being 22 to 40. Where the tension is over 50 a preliminary iridectomy is advised and extraction postponed. Routine use of the tonometer reduced choroidal hemorrhage to 1 case in 1923 and 3 cases in 1924. It is not clear from the text whether a distinction is made between glaucoma secondary to cataract, cataract secondary to glaucoma, or cataract appearing as in accidental complication of glaucoma. In operating for cataract it is of vital importance to determine the tension or a predisposition to it and it is pleasing to see an author stressing one of the most important of the large group of outside influences (as distinguished from the purely technical) which determines failure or success. The author discusses the drawn-up pupil so frequently seen after both 'expression' and 'capsulotomy.' Advocates of 'capsulotomy' would consider the boat-shaped pupil rare, unless the suspensory ligament has ruptured. The writer considers that the typical boat-shaped pupil is met with in cases where the vitreous is in contact with the iris. The drawn-up pupil of capsulotomy is most often due to forward displacement; that associated with 'expression' to inversion or recession. The author seeks an explanation of the way in which the drawn-up pupil continues to become more and more up drawn. The phenomenon is probably for the most part due to the progressive contraction of fibrous elements, associated with the processes of repair.

"Dr. J. Macphail writes a very interesting paper on 17,000 cataract extractions performed by him in the past 34 years at Bamdah Mission Hospital. From small beginnings the number gradually increased and in 1924 rose to 1,440. Numerous other eye operations are performed. His long and extensive experience makes his opinions of considerable value. The capsulotomy method is mostly employed, but he considers the Smith operation when successful a beautiful one and especially indicated in immature cases. Primary capsule rupture with the knife was adopted from Pope in Madras (where Drake Brockman introduced it in 1879 and it is still done, but with the needle). Irrigation is not employed, Pagenstecher's lens expressor being used to remove debris. A preliminary iridectomy is considered best in cases of high tension and if time were no object Dr. Macphail would do preliminary iridectomy in any case as it is safer. He has a lively sense of the danger of glaucoma and considers inactive pupil almost as important as a tonometer reading. An observer of Dr. Macphail's experience must also attach great value to the depth of the anterior chamber, the diameter of the cornea, and iris pigment disturbance. The writer considers that tonometers are of doubtful value in slight deviations from normal unless the observer and instrument are constants. The instruments of Schiotz,

McLean and Baillart give widely different readings in mm. of Hg. and obviously cannot represent in mm. of Hg. the intra-ocular pressure. In tension cases he considers preliminary iridectomy essential, and in the vast majority of other cases desirable. Like many operators in India he considers that the Indian patient behaves well on the table. There seems to be a widely prevalent idea that the Indian patient is quieter at the time of operation than the European. (This has not been the writer's experience.) Macphail considers (as do most others) that the Indian hospital patient is very difficult to manage after operation. It is interesting that he believes the main cause of cataract is glare and it would be instructive if he could produce figures to support the opinion that most cataract cases come from the hot dry regions and relatively few from the moister cooler districts. Without figures it is impossible to discuss this aetiological hypothesis.

"Like most mission hospitals in India the Bamdah Mission does magnificent work at a ridiculously small cost, the expenditure in 1923 being Rs. 3,600.

"Wright describes a method of adopting a paraffin artificial eye to a normal or reconstructed socket. In India it is difficult to fit patients with suitable double shell glass eyes, but one can model the exact size required in hard paraffin and then make a plaster mould, and cast several of like size and shape. The patient wears one, whilst another is sent away to be copied, details of colour, size and position of cornea (relation to the lid margin), and diameter of pupil being supplied to the manufacturers.

"Wright and Taylor contribute an article on *orbital cellulitis* which contains a number of practical points on treatment. In their opinion the diagnosis and treatment of the condition is not sufficiently appreciated and they have seen 'both eyes and lives lost through ignorance' of how to deal with such cases. The subject is not dealt with very well in the ordinary text books and their experience may be helpful to others.

"Wright publishes elsewhere an interesting case of optic neuritis in sphenoidal sinus disease, and describes a method of determining the outline of the sphenoidal cells by bismuth packing and x-rays. He records a cyst of the iris successfully treated by means of aspiration and subsequent filling with pure carbolic (which is finally removed) so as to destroy the lining cells. A good result in such cases is very rare and the technique described is new although similar methods have been used. The patient's eye was quiet a year after operation. He describes a case of Parinaud's syndrome in which the histo-pathological appearances suggested a conjunctival infection with Verhoeff's streptothrix, but Verhoeff, from examination of some of the material sent to him, did not confirm the type. He also contributes cases of amyloid degeneration of the conjunctiva; orbital growths of doubtful nature with detailed histo-pathology; and a rare bilateral congenital malformation of the cornea and conjunctiva (in which the bulbar conjunctiva had remained as embryonic skin).

"In the 1924 report of the *Government Ophthalmic Hospital, Madras*, Major Wright reviews 1,493 cataract operations. The vitreous loss rate, 0.2 per cent. approximately in a series of over 500 selected for peripheral iridectomy, is low. Compared with a series of nearly 800 cases with complete iridectomy and a vitreous loss rate of approximately 2 per cent., it indicates what can be done by selecting cases. Iris prolapse or impaction was met with in 6 per cent. The difficulty of recording results so as to give an absolutely clear idea of complications is mentioned. 'The only satisfactory way is to see patients after a year or so.' The difficulty of dilating deeply pigmented eyes is discussed with local causes and the possible influence of hypoadrenia. The tendency in Madras is towards complete iridectomy in 'doubtful' eyes, peripheral iridectomy in average good eyes, and a 'simple' in cases with light coloured irides of good tone (otherwise uncomplicated). Trephining for glaucoma was done in 112 cases and is still the operation of choice. Large numbers of glaucoma

cases in advanced stages are seen and these give the impression of important physical changes in the vitreous. The refraction department dealt with 2,644 cases out of which 356 fundus cases were of sufficient interest to merit special record. More than 50 per cent. had syphilis and arterio-sclerosis was present in approximately 12 per cent. The out-patient department showed high figures for certain conditions of serious prognosis for sight: trachoma 803, phlyctenular conjunctivitis 703, ulcus serpens 112, gonorrhoeal ophthalmia 79, keratomalacia 63 and panophthalmitis 98 (chiefly due to small-pox, gonorrhoea, keratomalacia, ulcus serpens and indigenous treatment for conjunctivitis).

Items of special interest and records of special cases are dealt with by the Superintendent and staff of the hospital. A bacteriological investigation of hypopyon ulcer in 75 cases with special reference to the pneumococcus was carried out in co-operation with Lieutenant-Colonel J. Cunningham, Director, King Institute, Guindy. The results showed that 28 of these were infected with the pneumococcus:—type I = 1, type II = 2, type III = 3, and type IV = 22. It was not anticipated that so many would fall into group IV. The investigation was designed to discover the frequency with which the different groups of pneumococci were present and to establish, if practicable, a method of treating ulcus serpens with high titre serum. The serum is at present under test. Iridocyclitis was performed in 10 cases at Colonel Herbert's request. The patients did well but the procedure did not show any advantages over trephining. In co-operation with Lieutenant-Colonel Cunningham, experimental work on trachoma was carried out. It was found impossible to infect the conjunctiva of *Macacus sinicus* with trachoma material, and rabbits inoculated subdurally gave a negative result. Sympathetic ophthalmia appears to be relatively infrequent in Madras. Dr. K. Koman Nayar maintained a record of 62 patients who would ordinarily be considered liable to sympathetic ophthalmia, but not a single case of infection has been traced. An interesting series of tape-worm cysts directly or indirectly affecting the eye or orbit is given. In one case the cysticercus was situated in the pupil and was easily removed through a keratome incision. The little bladder worm on extraction was about 3×5 mm. and whilst under observation in warm saline with a binocular microscope, it was observed to protrude its head and make movements of the rostellum. The specimen sent to the Royal Veterinary College, London, was identified as *cysticercus cellulosa*. A comprehensive series of cases illustrating different varieties of proptosis as met with in the out-patient department is listed by Mr. Kandaswami Pillai. It is noted that no case of Grave's disease was seen in the last 100,000 out-patients. One man showed the 'sun gazers' macular injury described by Kirkpatrick and the damage was found to be due to looking at a heliotrope through a theodolite. A number of cases of simple optic atrophy associated with syphilis without evidence of other systemic nervous system disease has been observed. Tabes with simple optic atrophy is rare. In the year under report, 8 cases of simple optic atrophy in which syphilis was definitely proved showed no other symptoms except (in some) an exaggeration of the knee jerk. It is considered that such cases represent a syndrome of relatively frequent occurrence. Epithelioma associated with extensive freckling in a young boy similar to that described by Hutchinson as lentigo maligna juvenilis is described and illustrated and a microphotograph shown. Other matters of interest are referred to in the report.

"Animal experiments carried out by Major Wright for Messrs. Collins and Mayou in connection with an investigation by them on siderosis were financed by the S. I. branch of the B. M. A.

"In losing Major Craggs, L.M.D., (for 17 years associated with the Government Ophthalmic Hospital) who has taken long leave prior to retirement, Madras loses an ophthalmologist who has done yeoman service to

promote the highest ideals of this science in South India. His contributions to ophthalmic literature date back to 1912.

"Lieutenant-Colonel Henry Smith (retd.) pleads for research in the treatment of *squint*. He suggests treatment of the lengthened muscles in non-paralytic cases by electrical stimulation and draws analogy between the treatment of eye muscles and that which is adopted for shortening, and lengthening of skeletal muscles. He quotes one case in support where an external squint of 30° was apparently cured by faradisation of the faulty rectus.

"Apart from the publications of workers in India, the outstanding features of the year may be briefly alluded to. Uribe Troncoso has almost perfected the *gonioscope* which by means of a corneal contact glass enables one to make a detailed examination of the filtration angle and the root of the iris and outer third of the anterior face of the ciliary body. The use of this instrument will be essential in large clinics, more especially in examination of preglaucomatous eyes.

"The exceedingly valuable work of Sir A. Lawson on *tints* and their values at last gives the Indian ophthalmologist something definite to work on. Crookes B₂, Ficusal, and Peacock blue all give a wide margin of protection against rays beyond either end of the visible spectrum and yet allow enough white light through for practical outdoor use in India. The ophthalmologist must use discretion in selection and it is not always desirable to use such deeply tinted glasses as the above. Unless patients feel the glare it is not considered necessary by the majority of experienced workers for normal persons to wear highly protective glasses, but with uveal or retinal disease, lenticular trouble or aphakia, it is nearly always desirable to order protective tints.

"Lindner's work on the phagocytosis of parasitic micro-organisms by the *conjunctival epithelium* is of the greatest importance and interest, and his method must form part of the routine technique of every up-to-date ophthalmic clinic. By making epithelial smears by Lindner's method one is frequently able to make a diagnosis before smears of conjunctival secretion are available, and when secretion smears give negative results an epithelial scraping is often positive. The idea that particular organisms were phagocysted by the conjunctival epithelial cells is not new, being noted by McKee in 1912, but Lindner in 1921 was probably the first to realise that the phenomenon was one of active phagocytosis.

"The Council of British Ophthalmologists published its annual report for 1924-25. Since its inception in 1918, this body has directed its activities into the most important channels in connection with ophthalmic education, standardisation of methods used in refraction testing, control of contagious disease, and questions of state on which expert ophthalmic opinion is necessary. The Council has published a series of valuable reports which have appeared in the *British Journal of Ophthalmology*.

"The Anti-Trachoma League, founded in 1923 at the Pasteur Institute, has directed attention to the importance of controlling the scourge. Since April 1, 1924, trachoma has become a notifiable disease in France. The need in India for some action on the part of the State in connection with the great groups of preventable eye diseases is obvious, but to expect the need to be officially met at a time when the existing medical machinery is being drastically axed is perhaps too much.

"*Papilloedema* has attracted much attention during the past year. In many cases surgeons are shy of doing decompression in time. In papilloedema of doubtful origin a subtemporal decompression in the early stages is indicated. From the ophthalmologist's point of view late operation is worthless, for even if it prolongs life and gives temporary relief, the nerve fibres suffer total strangulation as the result of late cicatricial changes. That marked papilloedema is compatible with perfect central vision seems to be a stumbling block to surgical

judgment. Localising symptoms of brain tumours excepting headache are most frequently conspicuous by their absence and when such causes of papilloedema as brain abscess, sinus infection, meningitis, nephritis, and diffuse intracranial syphilis are excluded there is little left to choose from. That we may have an appearance indistinguishable from papilloedema is familiar to every ophthalmologist of experience, but with papillitis, and optic neuritis with oedema, the vision and fields are, as a rule, disturbed early. Pseudoneuritis (as in high hypermetropia) is perhaps the most difficult appearance to contend with in differential diagnosis.

"New observations and investigations with the *corneal microscope and slit lamp* constitute a feature of the year's ophthalmic literature. Of English ophthalmologists, Graves is the only one who has advanced our knowledge in this branch and kept pace with continental workers."

In addition to Major Wright's review, Dr. H. T. Holland writes from Quetta as follows:—

"As I have been away on leave, I have not much to contribute, but I would refer to a modification of Smith's method, of which we did over 600 cases. Instead of a complete iridectomy, a peripheral iridectomy was performed. This is a very great advantage from the cosmetic effect, as there is a central pupil, instead of the U or boat shaped pupil to which exception is taken. This operation when successfully performed is almost ideal; the lens is delivered without any difficulty. There is however one drawback. Should vitreous present or the capsule be ruptured or the lens be dislocated backwards, it is difficult to introduce the vectis or spoon where a complete iridectomy has not been performed. In such cases the iridectomy has to be made complete, the vectis or spoon is then introduced, and the lens extracted with the spoon according to the Smith technique."

Attention may also perhaps be called to an interesting paper by Lieutenant-Colonel R. H. Elliot, (retd.), on *conjunctivitis in the tropics*. In epidemic form a great variety of micro-organisms is encountered, and the epidemic seems to be made up of a series of sub-epidemics, each with its own rise and fall. Secondly should be noted the curious seasonal regularity with which such epidemics repeat themselves each year. With regard to gonococcal conjunctivitis, the tropical form is usually contracted from conjunctival and not from genital infection, and is frequently sub-acute or chronic, with definite seasonal variations. It may become epidemic when the temperature rises, and in India and China is especially prevalent in July to September. The disease is on the whole far less virulent in the tropics than in Europe. During a severe epidemic in Samoa, Hunt implanted the virus from the eye on to healthy conjunctivae, the male urethra, and the vagina. Membranous conjunctivitis, rare in Europe, is common in the tropics. It is due to the Klebs-Loeffler bacillus, but may also be caused by staphylococci, streptococci, pneumococci, gonococci, or the Koch Weeks' bacillus. Sometimes small limited epidemics occur. Infection is spread by direct contact, flies, diphtheria carriers, and dust, and the disease is not infrequently contracted in out-patient departments. It is unilateral or bilateral; ocular paresis may occur; corneal ulcer ensues in some 63 per cent of cases. The treatment should consist of segregation and keeping away flies, antidiphtheritic serum, a eusol lotion and application of 2 per cent. silver nitrate to the lids.

The definite occurrence of swimming bath conjunctivitis shews that conjunctivitis may follow bathing in the contaminated waters of the tropics. Pediculous conjunctivitis occurs, and there is often a close association between pediculosis and phlyctenular conjunctivitis. Koch Weeks' conjunctivitis is of importance in lands where trachoma is rife, and Nicolle, Conseil and Cuenod have been studying the possibility of prophylactic inoculation, both subcutaneously and subconjunctivally.

Three other short papers also perhaps call for remark. E. Charles describes an epidemic of acute purulent ophthalmia in Gujranwala district, children being especially affected, and 12 cases seen within a fortnight. The disease began as an acute conjunctivitis followed by panophthalmitis, and all 12 patients became blind. Treatment proved quite ineffectual. S. K. Mukerjee records two cases of herpes zoster ophthalmicus, both in old men. In the first there was total destruction of the eye from rapid perforation and prolapse, the second patient recovered completely with a clear cornea and good vision. In both very severe neuralgia persisted long after the subsidence of symptoms. The same author also records a case of extensive glioma of the right eye in a child aged 1½. Exenteration of the orbit was performed, but the growth recurred, and also affected the left eye. A still further case recorded by the same writer is one of a curious syphilitic ulcer of the upper eyelid, with the characters of a tertiary lesion.

MEDICAL ENTOMOLOGY.

Dr. C. Strickland, Professor of Medical Entomology, Calcutta School of Tropical Medicine, reviews the year as follows:—

"As in last year's review, we may divide the literature on medical entomology into two compartments, one particularly affecting the clinician, the other the sanitarian.

Under *clinical entomology* the following papers may be noticed under a systematic classification, thus:—

Pathological lesions due to,

Chatopoda (leeches, flukes, etc.). Youbert has reported on a case of haemorrhagic dermatitis surrounding the site of recent leech-bite scars during an attack of malaria. The rash was excessively painful, with exacerbations carrying on for about 15 days, when it subsided. The interaction of the virus of malaria and leech bite was thought to have caused the condition.

Arachnids.—Baeng in America has studied the effect on the human being of the venom of *scorpions*, whilst Frety has confirmed previous observers who asserted that glycosuria occurs after scorpion sting. In treatment of this condition, Sharp recommends hypodermic injection of novocaine and adrenalin.

Pillers notes infection by *tongue-worms* (Linguatulide) of the human mesenteric glands, which might have been diagnosed as tuberculous.

Sequeira has made an important and useful review of some of the *mite* affections which are so common in man and domestic animals. He states that whilst *Demodex folliculorum* is generally considered harmless to man, it may cause a secondary infection giving rise to a 'ring' impetigo.

Chilopoda (Centipedes).—Baeng has studied the effect on the human being of the venom of centipedes.

Hexapoda (Insects).—*Flies*. Myiasis by the maggot has been reported by Porter from open wounds and sores, the ear, and freshly passed faeces. The maggots of both the common housefly (*Musca domestica*) and the lesser housefly (*Fannia scalaris*) have been found by Frison and Forscue respectively to infect the human intestine, sometimes causing vomiting. Desoill has produced a paper on the point, asserting that the eggs of the housefly cannot cause infestation, as they rapidly die in the gastric juice. Heras has reported an interesting case of infestation of man by the oxwarble fly (*Hypoderma bovis*), probably while the patient lay asleep in the open air. Migration of the larvae in the tissues extended from the shoulder to the abdomen and lasted for six months.

In the *public health* compartment must be included papers on systematic entomological work, between which and those of more direct importance to hygiene no hard and fast line can be drawn.

Mosquitoes.—Lieutenant-Colonel S. R. Christophers has produced a most valuable catalogue of the world anophelines, giving their synonyms; and his very important contribution should be of great utility in standardising discussion on the anopheline aspect of malaria. In another paper, he has established further varieties of common Indian anophelines.

Barraud has continued his studies and reports of the Culicine group in a series of papers, illustrated with most beautiful plates.

With regard to distribution of anophelines, Aserappa has contributed the result of a survey of the environs of Colombo, and Haworth in East Africa has discovered mosquitoes breeding in the axils of coconut palms.

On the subject of mosquito transmission of malaria, Gill has published a pleasantly philosophic paper on *A. rossii* Giles. He concludes that an answer to the question is still to seek.

Sinton and Little made another record of a species of *Culicoides* attacking the mosquito and sucking its juices, and revert to the idea that if the species can also bite man it may be a factor in the propagation of malaria.

Barzildai and others have made the interesting observation that the malarial parasite, after 82 sub-inoculations given for general paralysis, can no longer infect the mosquito. This opens up a wide vista in the study of the epidemiology of insect-transmitted diseases.

Walker has made some important observations regarding filariasis in Queensland; that *Culex fatigans* is the most efficient intermediate host, while other species may be relatively inefficient, depending on external conditions; yet others are killed by the development of the parasite, which in some species invariably dies.

Fleas and Plague.—Sinton has reviewed the diagnostic points of the Indian rat fleas, and has prepared a table thereof suitable for the general practitioner who has to deal with plague.

Hirst, continuing his important researches in Ceylon on the epidemiology of this disease *vis-à-vis* the species of rat fleas concerned, found that 98 per cent. of those in plague-free districts are *astia*, while in the endemic plague zone 30 per cent. are *cheopis* (this including a rate of 75 per cent. *cheopis* in the Customs' premises and granaries). This is yet another example of the highly specialised habits of the flea. Hirst thinks that *cheopis* flourishes better at a lower temperature and higher humidity. Experimental plague infections with *astia* were tried by working with it in an artificially cooled room. One out of 60 became 'blocked' and transmitted the disease. Both species diminish in the hot weather and *cheopis* is then less pathogenic; *astia* is a very indifferent man-biter.

On the sanitation side, Flu in Java has reviewed the measures taken to prevent plague. He does not favour fumigation with sulphur dioxide. Lal and Tiwari have tried fumigation by cresol; they state that the fleas in the rat runs (burrows) are not affected by it, though it kills off any rats which cannot get away from it.

Ticks and other mites and pseudo-typhus.—Nagayo and others in Japan have found that subcutaneous inoculation of the virus of Japanese pseudo-typhus led to no local reaction, as do mites which transmit the infection; on the other hand intradermal inoculation of the virus does produce a local reaction and lymphatic symptoms.

Walsh and Keukenschrijver in Sumatra think the rat to be the reservoir of the virus, as during an epidemic its average spleen is 1.7 times the normal size, but the animal does not get ill. Rats harboured *Trombicula deliensis* which also attacks man. Emulsified *deliensis*, injected into gibbons, produced an illness of the same nature as that produced by the injection of blood of pseudo-typhus cases.

Sandflies.—Sinton has continued his systematic researches on the structure of *Phlebotomus* species, and reports that the distribution of *P. argentipes* lies along the East Coast of India below 1,500 feet; he has also

reviewed the general relationship of *Phlebotomus* to diseases in India. Assistant Surgeon R. O. A. Smith, I.M.B., has described the methods which he has found best for breeding and raising *P. argentipes*.

Muscoid flies.—Patton and Senior White have catalogued all the oriental species of the genus *Musca*. Greene has described the puparia and larvæ of some Sarcophagids (flesh-flies). Simmonds concludes that certain ants, by preying on the maggot, keep the house-fly under control.

Cockroaches.—Sambon has continued to assert his belief in the connection of cockroaches and cancer, while Goodwin urges that more attention should be devoted to the eradication of this pest. Rau has devoted a paper to the study of its biology. Cameron finds a mixed powder of 4 parts of sodium fluoride to 1 part of boracic acid, sprinkled over the floors of a house and left for a fortnight, to be an effective blatticide.

Bugs.—Collier has reiterated the comparative unimportance of bugs as transmitters of disease; concluding that mechanical transmission may sometimes occur in plague and leprosy.

Miscellaneous.—Jucci has reviewed the work done on immunity of insects to pathogenic agents. Hutchinson has described fully his technique for the study of insect histology in the bed-bug.

Reynolds prefers formalin vapour to hydrocyanic acid gas for disinfection of premises from pests.

In addition to Dr. Strickland's review, a few other papers call for note. In view of the growing importance of sandflies as the vectors of sandfly fever, and probably of oriental sore and of kala-azar, Major Sinton's very fine series of papers dealing with the identification and distribution of species, methods of collecting and preservation, and anatomical notes on sandflies, published in the *Indian Journal of Medical Research* are of great value.

The discussion on the "insect menace" at the Indian Science Congress in 1925 was fully reported in our issues for April and June of last year. Lieutenant-Colonel F. P. Mackie read the introductory address; and a considerable number of well known entomologists took part in the discussion.

Major W. S. Patton (retd.) and Dr. H. A. Cookson record an interesting if not unique case of cutaneous myiasis caused by *Musca domestica*. An old man of 80 with varicose veins and ulcers was accustomed to sit crouched up over a fire. He had a small "hole" above the internal malleolus. Maggots of *Musca domestica* were found emerging from this ulcer, and on examination proved to be first and third instars. A female *Musca domestica* must have laid its ova in the ulcer. Major P. S. Mills records a curious case of persistent priapism in a Mahomedan boy aged 11 after the bite of a "chharbinda" (apparently a species of dung beetle).

TROPICAL DERMATOLOGY.

Thanks to the tremendous increase in the work at Major Acton's skin diseases' clinic at the Calcutta School of Tropical Medicine, and the continued introduction of aetiological investigation and classification into this confused subject, we may this year perhaps elevate "skins" into "dermatology"—a more exact science. The number of papers published during the year was considerable.

Major Acton deals with giant urticaria, or Quincke's oedema. This is an oedema of the deep fasciæ produced by the action of certain pressor bases derived from the food, acting in certain susceptible individuals with a lowered defence mechanism, either of congenital or of acquired origin. It is commoner in India than in Europe. Its age distribution is peculiar. It may occur in young infants who become hypersensitive to milk; or in adults who become susceptible to such foods as beef and pork. The swelling usually occurs some six hours or so after the ingestion of the particular food

concerned. A table of 20 cases is given where the food sensitiveness had been demonstrated by dermal tests. Lowering of the endocrine functions and hypersensitiveness of the sympathetic system are also factors in its causation. The treatment should demand in the first place the dermal tests to ascertain to what food-stuff the patient is susceptible, and cutting off this article of diet; whilst the stools should be examined for *E. histolytica* infection or other source of ulceration and absorption from the gut. The chief drug to use is adrenalin, at first given hypodermically till a full effect has been reached; then by the mouth as a combination of thyroid and suprarenal extracts.

The commonest mistake with regard to this but little recognised disease is to diagnose abscess and operate on it; or to mistake it for filarial lymphangitis.

Dr. G. Panja, from Major Acton's clinic, contributes a series of papers. One deals with superficial *pustular folliculitis* and is very well illustrated. The disease runs a course of papule eruption, pustulation and desquamation. There is itching but no pain, and the condition especially affects the legs and thighs. A *Staphylococcus aureus* was isolated from cases and produced similar lesions when a culture was rubbed into the shaved abdomen of a rabbit. The disease especially affects male adults. Treatment consists in keeping the parts dry; a lotion of hydrarg. biniodide in spirit; dusting powders and keeping the parts bandaged to prevent scratching and irritation. Depilation by x-rays is an excellent line of treatment.

The same author deals with *lichen spinulosus*, of which four cases are described. The lesions consist of symmetrically distributed groups or patches of sago-grain like papules, surmounted by filiform spines, arising from the hair follicles and situated most commonly on the abdomen and the back of the shoulders near the axillae. Scrapings shewed fungi of the *tinca* group. These cases are very resistant to treatment; but vigorous scrubbing with soap and hot water, and applications of rectified spirit, tincture of iodine and of salicylic acid ointment, 1 drm. to 1 oz., may be tried.

The same author describes some interesting cases. One was one of generalised blastomycosis in a Hindu girl aged 8, with a ++ Wassermann reaction. The diagnostic points about the condition are patchy lesions with a healing centre and pustular spreading margin. Fungi were discovered on examination of scrapings by the liquor potasse method. X-rays constitute the best line of treatment, but potassium iodide may be given in large doses, and unguentum hydrarg. ammon. dil. A second case was one of melanoderma in a Hindu male aged 19, with a negative Wassermann reaction. Yeast-like organisms, the so-called spores of Malassez were found. The condition present was one of discrete small round black spots, chiefly on the abdomen. Treatment of the condition consists in the use of sulphur soap, a bismuth and hydrarg. perchloride lotion, and touching the spots with trichloroacetic acid. A third case was one of malignant pustule of the left arm near the axilla in a hide worker, in which the specific bacilli were demonstrated, but no typical black scab was seen even after 12 days' duration of the disease. A fourth case was one of multiple soft fibromata of the face with a facies simulating that of nodular leprosy, and isolation of a diphtheroid bacillus from the lesions. An even more extreme case of a similar condition is recorded by (Dr.) Mrs. E. B. Carr, of a woman aged 40 whose whole body was covered with multiple neuro-fibromata, the condition dating from early childhood. One breast was so infiltrated as to be enormously hypertrophied, the nipple being 10½" from the chest attachment. On amputation the breast weighed 3½ lbs.

Lieutenant-Colonel J. Cunningham and S. Ramakrishnan have investigated the types of streptococci in lesions of the skin and mucous membranes. Of 141 strains isolated and examined hæmolytic varieties were slightly in excess of non-hæmolytic. Of the hæmolytic varieties the *sub-acidus* and *anginosus* strains were most

common; of the non-hæmolytic strains *agnavus*, *salivarius* and *mitis* types.

(The reviewer may perhaps be permitted in this connection to draw attention to the great importance of hæmolytic streptococci in general medical practice in the tropics. They are the usual cause of puerperal fever in India; they are the causative agents of many acute dermal and ocular lesions; in the gut a secondary infection with hæmolytic streptococci may follow an infection with *E. histolytica* and cause all sorts of unexpected symptoms by invading the blood stream; they are probably associated with the acute endocarditis of certain fevers of Bengal; during the great influenzal pandemic, as seen in Assam in 1917-18, the reviewer found them almost constantly present in all sputa cultured; and considered that they were an important pathogenic feature of the outbreak—although other workers had an entirely different experience; they are the organisms most commonly found in the almost epidemic sore throat which invades Calcutta city every cold weather; they may have something to do with the pernicious type of anæmia encountered in sprue. In brief, hæmolytic and infective strains of streptococci appear to abound in the Indian atmosphere.)

Major J. F. James, writing from Kohima, advocates a treatment for *Naga sore* and *ulcus tropicum* which he has found very successful. Bits of lint quarter of an inch thick, made to fit the ulcers or slightly overlap them, are soaked in a 25 per cent. solution of magnesium sulphate, applied and covered with oiled silk or plantain leaf. If the ulcer be very foul preliminary cleansing with hot permanganate baths is advisable. The dressing must be properly applied and the waterproof covering must overlap the soaked lint to prevent evaporation. This dressing is very cheap, painless, and efficacious.

P. B. Ran advocates the use of *bouchi*—(*Psoralea corylifolia*)—in leucoderma. A favourite application of it in Ayurvedic medicine has the following composition; yellow orpiment, 1 part; *bouchi* seeds (ground up presumably) 4 parts; made into a paste with fresh cow's urine. Probably water may be substituted for cow's urine.

Captain D. M. Bhatavadekar describes a case of multiple nevi in an Indian male, aged 25. One naevus occupied the area over the left scapula, shoulder, axillary and thoracic regions and measured 25" X 10"; a second extended from between the scapulae to the occipito-perieto-temporal junction, and was 12" X 9"; there were some 20 hairy moles, 1" to 4" in diameter scattered all over the body; about 200 small moles similarly distributed; small pigmented patches on the palms and the hard palate; whilst the left half of the scrotum was empty and the patient had phimosis. The whole condition was of congenital origin. Flat, raised and fatty moles were all present simultaneously. The distribution of the lesions did not in any way correspond to any innervation areas but appeared to be universal and scattered.

Mr. R. L. Spittel, F.R.C.S., in a most interesting article, describes the art of the Indian *chiroprapist*. His little handbag is the only thing respectable about this intriguing rogue, although his "chits" are usually highly laudatory. His armamentarium consists of a sharp oblique-edged chisel made from an old Kropp razor, used for thinning down the corn; a probe; and an assortment of conical horn cups. These latter are applied to the corn after it has been thinned down, suction is made by the lips and the little aperture at the conical end of the cup sealed with wax. His technique is of course intensely septic, but it is surprising how much relief it affords. On the other hand the complete removal of the epidermal plug is beyond him; he does not attempt it.

Assistant Surgeon R. W. Scanlon, I.M.D., describes a case of acute dermatitis due to the use of marking nut, and such cases are probably not uncommon in India, though infrequently reported in the journals.

Marking nut juice was applied by the patient for treatment of ringworm of the scalp. Four days later there was acute erythema and vesication over the biceps area of the left arm which had come into contact with the anointed scalp.

PATHOLOGY, LABORATORY METHODS, VACCINES, SEROLOGY, ETC.

Priority of place must certainly be given to Sir Leonard Rogers' exceedingly interesting review of *pathological evidence relating to disease incidence as seen in Calcutta*, published in the *Glasgow Medical Journal* during the year. Here a careful comparison is made between the analysed results of 1,600 consecutive post-mortem examinations made at Calcutta in comparison with 1,000 consecutive post-mortems made at St. Mary's Hospital, London. Considerations of space prevent our doing more than quoting the author's conclusions, and the paper has already been fully dealt with in our *Current Topics* section in 1925. Sir Leonard's conclusions are as follows:—

"1. Both the post-mortem records and the vital statistics of Calcutta show that one-third of the mortality is due to tropical diseases, and two-thirds to those of world-wide distribution.

"2. The age incidence shows four times as many deaths in persons over 50 years of age in the London as in the Calcutta post-mortems, and this proportion is the same when the purely tropical diseases are excluded from the calculation.

"3. The Calcutta figures show a great excess over the London ones in deaths from septicæmia, tetanus, tuberculosis, lobar pneumonia, non-tubercular meningitis, and cirrhosis of the liver—the first, fourth, and fifth being caused by the streptococcal group of organisms, which are favoured by the high mean temperature and overcrowding in the houses.

"4. The London series shows a marked excess in the case of circulatory diseases, especially in the case of rheumatic endocarditis and mitral stenosis secondary to it, which is nearly, if not quite, absent in Bengal; and to a less extent in atheromatous disease including aneurysms, due to the age factor, as atheromatous changes have a very similar age incidence in different decades of life in both series, and afford no evidence of especially early degenerative arterial affections to account for the shorter life of the Bengal race, while cerebral hæmorrhages are also much more frequent in the London series, also on account of the age factor.

"5. The four-fold excess of cirrhosis of the liver in Bengal cannot be explained on the alcoholic theory of its causation, as that is a very small factor in India, but evidence is produced that it is secondary to chronic ulceration of the gastro-intestinal tract, chiefly in the form of long-standing amœbic dysentery.

"6. The Indian races in Bengal have a lower resisting power against many specific diseases, such as pneumonia, cholera, dysentery, tuberculosis, fevers, etc., which are the most frequent causes of death in them, than Europeans living in Bengal, which is the main cause, in addition to the prevalence of tropical diseases, in their low expectation of life; and is probably due partly to low racial vitality, most likely associated with the custom of early child marriage, and partly to insanitary conditions."

With regard to the vexed question of the incidence or relative non-incidence of cancer in Asiatic races, Sir Leonard concludes as follows:—

"1. Malignant tumours, including both connective tissue and epithelial types, are about equally common in Bengal and England, with a slight excess in the tropical country, quite contrary to the statements of those who maintain that civilised races suffer eight times as much from them as uncivilised primitive peoples.

"2. Both innocent and malignant connective tissue tumours are considerably more common in Bengal than in England, while the reverse is the case with both innocent and malignant epithelial tumours; which supports the view that the innocent forms shade off into or may take on the characters of malignant ones.

"3. The slightly lower incidence in Bengal of the malignant epithelial tumours or carcinomata is fully explained by the age factor, as the higher rate in London is more than accounted for by the great excess of persons of the cancer age of over 40 or 50 years in England as compared with Bengal.

"4. Cancers of the tongue, œsophagus, stomach, large intestine, and breast show considerable excess in the London pathological examinations, while those of the skin, penis, both the cervix and body of the uterus, liver, and gall-bladder are in excess in India, nearly all of which are explainable on the known laws of long-continued irritation being the most important predisposing or exciting cause of cancer. This relationship is strikingly illustrated by the figures given, showing that gall-stones and cancer of the gall-bladder are rather more common in Bengal than in London, for it has been proved experimentally that the presence of gall-stones may induce cancer formation in this viscus.

"5. The three-fold excess of cancer of the uterus in Bengal is probably related to early menstruation, child-bearing and menopause in the Bengali race leading to earlier and more frequent development of cancer in them as compared with European females.

"6. In future, the onus will lie on those who proclaim the rarity of malignant growths in uncivilised races of proving their assertions by extensive and accurate pathological data, such as those on which the above conclusions are based, for about 90 per cent. of the Bengal population who furnish a large proportion of the Calcutta hospital cases, live in villages under primitive conditions, and on a diet of natural foods."

A useful cheap pattern of hypodermic outfit is described in our issue for January 1925 by Dr. J. W. Tomb. The studies on laboratory technique, copiously indexed and cross-referenced, by Lieutenant-Colonel W. F. Harvey were continued during the year in the *Indian Journal of Medical Research* in all four numbers published during the year, and this monumental and most useful reference book may perhaps become available as an inclusive volume in the near future. H. Ghosh has studied the *action of certain chemicals on bacteria*. He finds that 1/640th of a c.c. of 30 per cent. magnesium sulphate solution exerts an attenuating effect when added to a culture of *B. proteus*, but when different amounts of a 20 per cent. solution of calcium chloride are added, this effect is inhibited. Similarly, 1/128th of a c.c. of a 4 per cent. solution of zinc sulphate has a similar attenuating effect, but this effect is again inhibited by the addition of different amounts of the same calcium chloride solution. The interaction of chemical substances in a bacterial culture, in other words, is perhaps of importance.

Major J. A. Sinton and A. C. Banerjea advocate the *thick film method of examination* in suspected malaria. Their technique is to take a thick film on one half of a slide, and a thin film on the other half. The thin film is fixed by dipping this half of the slide into methyl alcohol. After drying, the whole slide is next flooded with diluted Giemsa's stain, the stain subsequently flooded off with distilled water, and the film allowed to dry in air. Over 10,000 films were examined in a year by this method. The relative numbers of parasites encountered were as 1 to 6 for thin and thick films in cases of *P. vivax* infection, and 1 to 20 in cases of *P. falciparum* infection. Major Sinton also deals with the so-called hæmogregarines of man. Bodies resembling hæmogregarines were found in 10 slides out of a batch of 50 examined. He agrees with Dr. Wenyon that such pseudo-hæmogregarines are in reality vegetable cells derived from the atmosphere and contaminating the slide.

Dr. P. Ganguli raises the question as to whether *Trichomonas hominis* is pathogenic or not. This protozoal parasite was found in 43 patients, of whom 36 suffered either from diarrhoea or dysentery. In 3 of the cases cultures failed to shew any bacterial cause for the disease. In 7 instances the parasite was present in a formed stool. He considers that infection with *T. hominis* is probably analogous to infection with *E. histolytica*; there may be a carrier condition or an acute lesion of the gut. Oleum terebinthinæ treatment appears to be successful. S. K. G. Dastidar records *Trichomonas* infection in the urine in 3 male and 1 female patient. Symptoms of mild urethritis were present which cleared when the trichomonads disappeared. (The whole question at issue is fully dealt with by Assistant Surgeon B. M. Das Gupta in our issue for January, 1926.)

From Madras, Dr. Turkhud reports that Dr. Sitapati has carried out a series of experiments with *B. coli* derived from both human and bovine sources, with a view to determining the possibility of grouping them on a serological basis. The enquiry is still in progress.

Vaccines.

Nand Lal comments on the use of carbolic acid as a sterilising agent for bacterial antigens. In the commonly used strengths of vaccines it will effectively sterilise the emulsion without the aid of heat. The time required varies with the strength of carbolic acid used and for different organisms. The same author deals with the viability of bacterial cultures. Efficient sealing up of cultures is an important factor in their preservation. The reaction of the culture medium is also important in connection with the duration of life of the bacteria.

Serology.

Major R. B. Lloyd, Professor of Serology, Calcutta School of Tropical Medicine, contributes the following notes:—

"No very striking advances have occurred during the year, though the discoveries of Gye and Barnard may possibly open the way to a serological attack on the cancer problem.

"In many parts of the world the various flocculation tests for syphilis have been examined, and with a few dissentients the large majority of workers are of opinion that while useful up to a point, the flocculation reactions with the possible exception of the Sigma reaction are inferior to the Wassermann test.

"Reports have now come forward chiefly from American sources that the new Wassermann technique introduced by Kolmer is very valuable. This is an important technical improvement. It is interesting to observe, as Wassermann work has become more and more accurate, that some diseases—other than syphilis—formerly thought to yield a positive Wassermann reaction have now dropped out of the list. In this list there are only two diseases left, viz., yaws and leprosy and it is believed that the new Kolmer technique eliminates leprosy.

"Our own results have indicated that the positive Wassermann reaction met with in leprosy is frequently due to syphilis. This opinion is based upon indirect evidence of various kinds. (1) The power of antisyphilitic treatment to remove in many instances the positive reaction in leprosy. (2) The fact that positive results with the Sachs-Georgi and Kahn flocculation reactions in leprosy run broadly parallel with the Wassermann positives. (3) The fact that the new Kolmer technique is reported to give negative reactions with leprosy when uncomplicated with syphilis. (4) The marked improvement clinically which some cases show under antisyphilitic treatment. No final judgment on this question can be given yet and further research is necessary. If this view is to prevail, we have to compare the percentage of positive Wassermann reactions in leprosy (about 40 per cent.) with that in the general

population, which we may put at 15-25 per cent. The difference is very marked, and if these reactions in leprosy are due to syphilis it would appear to indicate that the latter is an important predisposing cause of the former, which will render the solution and control of the leprosy problem no easier.

"In connexion with blood grouping work, attention has been focussed on quantitative direct matching tests between the recipient's and donor's bloods mixed together under *in vitro* conditions approximating to the *in vivo* conditions obtaining after a transfusion. The importance of this lies in the fact that transfusions may be carried out on a scientific basis without previous grouping as a laboratory procedure.

"Use has been made of the specificity of precipitin antisera to determine the precise nature of the blood upon which blood-sucking insects have fed. This enables workers upon insect-borne diseases to concentrate attention on those insects known to feed on man as possible vectors of such diseases as malaria and kala-azar."

With regard to the Wassermann reaction, Dr. Turkhud reports that Dr. Ramakrishnan is at present engaged in Madras in making a comparative study of the Kahn's precipitation and the Wassermann tests.

Major L. A. P. Anderson and Major Sinton report the results of 63 cases tested one to three hours after the administration of adrenalin by injection by the Medical Research Committee's Report (1918) No. IV method. Doses of one mgm. of adrenalin failed to make a negative Wassermann reaction positive. In our issue for January, 1925, Major Lloyd deals fully with the comparative results of different serological reactions to-day in use for the serological diagnosis of syphilis.

MEDICO-LEGAL NOTES.

The only paper of interest during the year was Major C. A. Godson's analysis of 660 post-mortem held at the police morgue in Calcutta during 1923-24. No less than 149 fatal street accidents were included, most of them due to reckless motor driving by the "Taxi Singhs" of the community. Suicide by burning is very common among Indian females. Opium proved to be the commonest poison in use and probably many cases classed as deaths due to an accidental overdose are really cases of suicide. In an interesting case of carbon monoxide poisoning three persons occupied the same room; the mother died, the father was admitted to hospital in an unconscious state but recovered, whilst a young child appeared to be entirely unaffected. A dose of 30 minims of extract of *nux vomica*, given by mistake for a corresponding dose of liquid extract of ergot, proved fatal, although such a dose only contains 2½ths of a grain of strychnine.

SERVICE NOTES.

Lieutenant-Colonel C. C. Murison discusses hospital administration, with special reference to the detaining of patients and to the record of diagnosis in hospital registers, in our issues for March and September.

Lieutenant-Colonel J. K. S. Fleming, Deputy Director-General, I.M.S., reviews the year as follows:—

"Since the service notes forwarded by Colonel Needham in November 1924 were written, the whole future of the Indian Medical Service has been in the melting pot, and the Secretary of State's announcement that the Indian Medical Service must be retained, although it would be essentially a military service, must have undoubtedly come as a relief to many.

Its reconstitution, in so far as the future employment of officers in civil, etc., is concerned, is now being considered in consultation with the local Governments, and orders in connection therewith will, it is expected, be issued in the near future. The rights of those at present in civil employ will, no doubt, be adequately safeguarded.

Memorials have, it is understood, recently been submitted to the Government of India from Indian members of the Service whose commissions are dated prior to 1st December 1925, praying that the concession of free passages to Europe and back which has recently been sanctioned by Government on the recommendation of the Lee Commission for European members of the Service may be made applicable to them: the matter is under consideration.

In the *Gazette of India* for May 1925 the following Royal Warrant was published regarding the age for compulsory retirement of an I.M.S. officer holding the appointment of the Director of Medical Services in India:—

George R. I.
Royal Warrant.

Whereas We deem it expedient in the interests of the Service to make the following change as to the age at which officers of Our Indian Medical Service holding administrative appointments shall be placed on the Retired List.

Our will and pleasure is that an officer of Our Indian Medical Service holding the appointment of Director of Medical Services in India shall be placed on the Retired List on attaining the age of 60.

Our warrant dated 13th June 1919 shall be amended accordingly.

Given at Our Court at St. James's this 17th day of March 1925, in the fifteenth year of Our Reign.

By His Majesty's Command.

(Sd.) BIRKENHEAD.

A conference of Inspectors-General of Prisons was held in Ootacamund in October 1925. The findings of the conference have not yet been published.

The Government of India have decided, with the approval of the Secretary of State, that military Indian Medical Service officers who are appointed to the *Medical Store Department* should remain under military rules for the purposes of privilege leave; and that the temporary charge pay of Rs. 50 p.m. admissible to Assistant Surgeons should be made definitely applicable to the charge of a Medical Store Depot in the absence, on privilege leave, of the permanent incumbent.

Government sanction has also been accorded to the raising of the salary limit laid down in para. 273(c) of *Pay and Allowance Regulations*, Part II, for the grant of Presidency house rent at Madras, from Rs. 1,400 p.m. to Rs. 2,500 in regard to officers of the I. M. S. in military employ.

Under Army Instruction (India) No. 401 of 1925, sanction was accorded to the grant of overseas pay in sterling to officers of the Indian Medical Service in military employ in accordance with the terms laid down therein.

Sanction has also been accorded in Army Instruction (India) No. 5-S., dated 25th July 1925 to the grant of leave passage concessions to military officers. The rules governing the same are published as an Appendix to the Army Instruction.

In accordance with Army Instruction (India) No. 912 of 1925, separation allowance is admissible to married officers of the R. A. M. C., I. M. S. (in military employ), Royal Army Veterinary Corps and Army Dental Corps, when their families are not allowed to accompany them to the station to which they are posted, for example frontier stations such as Razmak.

Under Army Instruction (India) No. 950 of 1925, regular executive officers of the Indian Medical Service, while on leave in India other than privilege leave

will receive pay at the following rates, to which full overseas pay will be added, when admissible.

	Rs.
Lieutenants	375
Captains:—	
During first 3 years service as Captain ..	500
With more than 3 years service as Captain ..	600
With more than 6 years service as Captain ..	700
Majors:—	
During first 3 years service as Major ..	750
With more than 3 years service as Major ..	900
With more than 6 years service as Major ..	1,050
Lieut.-Colonels:—	
Until completion of 23 years total service ..	1,200
During 24th and 25th year of service ..	1,300
After completion of 25 years service ..	1,400
When selected for increased pay ..	1,550

These rates will have effect from the 1st January 1926.

Under India Army Order 693 officers proceeding on privilege or combined leave ex-India may draw privilege leave pay either in advance or in arrears in the United Kingdom. Privilege leave pay when drawn in the United Kingdom is payable in arrears only.

In accordance with Army Instruction (India) No. 662 of 1925, an outfit allowance of £50 is admissible to officers granted permanent commissions in the Indian Medical Service on or after 1st July 1919 and to future entrants. The allowance will be reduced by the amount of any outfit allowance already drawn by such officers in respect of any previous commissions held in the Indian Medical Service or any other arm of Service, if they were appointed before the 20th December 1923. For officers appointed on or after that date, the allowance will only be reduced if they held the previous commissions within three years of the date of their permanent commission in the Indian Medical Service.

Under Army Instruction (India) No. 410 of 1925, when a British medical officer is ordered by a competent authority to proceed to another station in India at which no British medical officer is available to attend the wife or a female member of the family of a British officer or British other rank, who is entitled to free medical attendance, he will be granted travelling allowance under the rules in Army Regulations, India, Volume X, as amended by Army Instruction (India) No. 573 of 1924.

In the event of the British medical officer being unable to leave his station, a competent authority may sanction the free conveyance of the patient to and from that station.

The present strength of the I. M. S. is:—

Permanent officers—	
European	507
Indian	164
Temporary officers—	
European	6
Indian	134

Up to the 3rd December, there had been no less than 34 officers lost to the I. M. S. during the year; the list being as follows:—

Died.—Colonel J. A. Black and Captain J. F. Holmes.
Resigned.—Captains H. Watts Taylor, A. L. Watts and A. F. G. Raikes.

Retired.—Colonels F. L. Blenkinsop, F. Wall and P. Dee.

Lieutenant-Colonels G. A. Jolly, H. Emslie-Smith, A. E. Walter, H. H. G. Knapp, R. A. Lloyd, O. St. John Moses, A. Leventon, A. T. Gage, A. M. Fleming, J. M. Woolley, J. C. G. Kunhardt, L. Hirsch, E. C. C. Maunsell, F. D. S. Payrer, R. Bryson, G. F. Marr, F. O. N. Mell, J. V. Illius, Sir D. G. R. S. Baker, Bart., H. A. F. Knapton, A. G. Coullie, and J. L. Marjoribanks.
Majors A. E. Grisewood, J. A. Cruickshank and G. H. Cross.

Invalided.—Major J. A. Horne."

CHOLERA IN THE PUNJAB IN 1925.*

AN EPIDEMIOLOGICAL NOTE.

By C. A. GILL, D.P.H., D.T.M. & H.,

LIEUT.-COLONEL, I.M.S.,

Offg. Director of Public Health, Punjab.

(1) *Preliminary Remarks.*—Before describing the recent outbreak of cholera in the Punjab, which, as will shortly be suggested, may possess a significance out of proportion to its magnitude, it is necessary to refer briefly to the recent history of cholera in northern India. In the year 1924 a recrudescence of cholera of unusual magnitude took place in the endemic home of the disease (Bengal, Bihar and Orissa), but as the Punjab is outside the endemic zone it was not directly implicated in this revived activity of the disease. This Province was, however, indirectly affected, since the incidence of cholera in the Punjab is closely dependent upon the annual importation of infection from the endemic zone. It should be explained that no permanent foci of cholera are known to exist in the Punjab and that in almost every instance outbreaks of cholera in this Province are directly or indirectly traceable to importation of infection from outside the Province. In the majority of cases the disease appears to be introduced by Hindu pilgrims returning from the great religious festivals held at Hardwar in the United Provinces, which place, it is understood, is constantly infected by pilgrims hailing from Bengal and Bihar and Orissa. The great fair held annually at Hardwar in the United Provinces has in fact long functioned, at any rate since the year 1867, as the immediate source of outbreaks of cholera in the Punjab, and in 1924 Hardwar again played its usual rôle, but in addition, the *Adh Kumbh Mela*, which was held at Allahabad in February 1924, was also in part responsible.

Mainly as the result of infection imported by pilgrims returning from these fairs, the Punjab, after two years of almost complete freedom from cholera, experienced a mild epidemic during the summer of the year 1924, with the result that 4,118 cases and 3,551 deaths occurred as compared with 25 cases and 11 deaths (all dependent upon importation) in the previous year, and 287 cases and 128 deaths during the year 1922. But although the mortality in 1924 was not great, 24 out of 29 districts and 56 out of 159 towns were infected.

The behaviour of cholera during the year 1924 was absolutely normal, its direction of spread being from the south-east to the north-west, its period of prevalence being confined to the months of July, August and September, and Hindu pilgrims being, as usual, the first to suffer. In November 1924, in accordance with custom, the disease disappeared completely from all parts of the Province and from this time onwards until the beginning of April 1925, the Province was, so far as is known, completely free from cholera.

The State of Kashmir and Jammu, which is located beyond the northern frontier of the Punjab at a considerable elevation above sea-level in the Himalayas, was also infected with cholera in the summer of the year 1924 in the same manner as the Punjab, i.e. by Hindu pilgrims returning from the pilgrim centres located in or near the endemic zone, but in Kashmir cholera behaved in a peculiar manner, since, contrary to custom, it continued to prevail throughout the winter of 1924-25 when the country was under snow and the thermometer was many degrees below freezing point. So absolutely without precedent (so far as the Punjab is concerned) did this appear that in January 1925, enquiries were made (but unfortunately they met with no response) from the medical authorities of Kashmir State as to the accuracy of the reports. Subsequent events however confirmed the diagnosis, since with the onset of spring (March) a definite recrudescence was followed by a severe and extensive epidemic of cholera which is reported to have caused up to the middle of August 1925, about 20,000 cases and 10,000 deaths.

(2) *Brief Account of the Punjab Epidemic.*—As already stated, the Punjab remained completely free from cholera up to April 1st, 1925, but on or about this date a small outbreak, which was not reported at the time, occurred amongst Muhammadans at a town (Pind Dadan Khan) situated in the north of the Province on the Jhelum river in the district of that name. Subsequent investigation showed that infection was conveyed from this place to an adjacent village in the Salt Range where a large fair attended by some 50,000 people was being held. Everything passed off well at the fair until it was about to end on April 12th, when an explosive outbreak of cholera involving several hundred persons broke out almost simultaneously amongst the pilgrims who were at that time dispersing (or about to disperse) to their homes. This is the usual course of events, since it is a rule to which the exceptions are few, that irrespective of the duration of a fair, cholera rarely breaks out until a fair is about to conclude. There are two possible explanations of this curious phenomenon; in the first place the earliest cases of cholera are rarely typical, and secondly, a strong tendency exists upon the part of all concerned to hide the existence of the disease as long as possible and more especially until the completion of the religious ceremonies that usually culminate in a

* Note.—An abstract of this report was prepared at the request of the Public Health Commissioner with the Government of India, for submission to the Office International d'Hygiène Publique at its session in October, 1925.

ceremonial ablution and drinking of the sacred waters on the last day of the fair.

The immediate source of the outbreak is thus traced to an unreported focus of infection in a neighbouring town, but the manner in which this town became infected—it had been free from cholera for several years—could not be determined. It is, however, probable that infection was imported by human agency from Kashmir State, one of whose boundaries is coterminous with that of Jhelum District. It is significant perhaps of the accuracy of this surmise that, on those rare occasions during the past 60 years when cholera has continued to prevail in Kashmir throughout the winter, Jhelum district is usually the first district of the Punjab to become infected.

The subsequent history of the Punjab epidemic was readily traced owing to the fact that the rest of the Province was completely free from the disease. There was in the first place an extensive infection of Jhelum district and of the adjoining districts of Shahpur and Gujrat by means of pilgrims travelling by road. Secondly, infection was rapidly transmitted over long distances by rail—many pilgrims developed cholera in transit—with the result that small outbreaks occurred in eight districts at a long distance from the primary focus. It thus came about that within the space of ten days about 800 cases and 320 deaths occurred almost solely amongst pilgrims in eleven different districts of the Province. As soon as the result of the original explosive outbreak subsided it became evident that secondary epidemics were taking place in many localities, all or nearly all of which followed—sometimes with remarkable rapidity—upon the arrival of an infected pilgrim. It should here be stated that, although the original outbreak had the explosive characteristics of a water-borne epidemic, the secondary epidemics were of small magnitude and confined almost solely to contacts or to persons who had shared the same food or drink (house infection) as persons suffering from cholera. A few secondary epidemics, however, exhibited fulminant characteristics, and in these outbreaks there was strong reason to believe that wells or small canals (which in certain localities constituted the sole source of water) had become infected with the germs of cholera. In one instance, for example, the corpse of a person who had died of cholera was found in a canal distributary, that formed the water supply of a village. Nevertheless, the character of most of the secondary outbreaks suggested "house-infection" rather than a water-borne epidemic. Some of these secondary epidemics acted in their turn as distributing centres, and in this manner the number of infected localities—each actively infective for a brief period only—gradually increased so that within three weeks of the first appearance of the disease 2,240 cases and 913 deaths occurred. From the middle of May onwards the disease began to decline and by the first week of June the epidemic had almost subsided. Early in this month, however, as the result

of a fresh invasion of cholera from the United Provinces, cholera appeared in certain hitherto uninfected localities in the extreme south-east of the Punjab. This circumstance caused a temporary rise in the weekly returns during the month of June, but it was short-lived and in the week ending August 1st only 37 cases and 15 deaths occurred throughout the Punjab. This second small wave of cholera which came from the United Provinces, would appear to represent both in regard to its source of origin and to its seasonal periodicity the normal characteristics of cholera in this Province, whereas the earlier outbreak constitutes an exceptional occurrence without precedent, both in regard to time and space, during the past 30 years. The total number of cases and deaths from cholera during the period from April 1st to August 8th, 1925, was 5,841 and 2,129, respectively.

The chart shows the weekly incidence of morbidity and mortality during the above period.

CHART.

Showing the weekly number of cases and deaths from Cholera in the Punjab during the period April 1st to August 8th, 1925.

(3) *Preventive Measures.*—As no instance of an extensive epidemic of cholera during the months of April and May is recorded to have occurred in the Punjab during the past 30 years, no particular apprehension was felt in regard to the occurrence of cholera in the Katas fair in April 1925, more especially as the Province was free from infection at the time. It has however since come to light as the result of a scrutiny of the Punjab Sanitary Reports during the period 1862-1881 that widespread epidemics of cholera have occurred, notably in the years 1867 and 1879, in the months of April and May—and it is now known also that these early epidemics in the north of the Province were frequently associated with the persistence of cholera throughout the winter in Kashmir.

In accordance with routine orders, arrangements were made a week before the commencement of the Katas fair under the personal supervision of the District Health Officer to disinfect and to protect the water-supply and to provide for the sanitation of the fair. The arrangements were, however, based upon the assumption that

the attendance at the fair would be normal, i.e., about 10,000 to 15,000 people, whereas it is calculated that about 50,000 persons actually attended the fair. In these circumstances it is not surprising that the water-supply arrangements should have proved inadequate and that people drank water from the sacred tank (which indeed forms part of the religious ceremony on the last day) and from polluted streams in the neighbourhood. It is obvious therefore that given a case of unreported cholera amongst the pilgrims, an explosive outbreak of the disease was only too likely to occur. As soon as the first case of cholera came to light on April 12th, the tank and streams were again disinfected, but the damage was then done and all efforts were therefore concentrated upon preventing the spread of infection by returning bands of pilgrims. On April 14th, when the first report regarding the outbreak reached the Public Health Department, a general warning was issued to the civil and military authorities, to neighbouring Provinces, to the railway administration and to the public, whilst orders were sent to all Medical Officers of Health and Civil Surgeons directing them to keep watch over pilgrims returning from the fair and to make immediate preparations to isolate and treat all travellers from the infected area presenting symptoms suggestive of cholera. District Health Officers were also directed to take steps to ensure that cholera outbreaks were promptly dealt with and to see that the "cholera depots" established in rural areas were equipped with medicines, disinfectants, and vernacular pamphlets explaining the nature of the disease, its mode of spread and treatment. Arrangements were also made to enable anti-cholera inoculation to be carried out on a large scale and the equipment necessary for this purpose and for giving intravenous injection of hypertonic saline together with potassium permanganate, kaolin and the essential oils mixture, was also provided. In collaboration with Civil Surgeons and Deputy Commissioners the medical personnel of every infected district was mobilized for the purpose of carrying out the above scheme. These measures were carried out vigorously and promptly and every infected locality was visited almost immediately by a medical officer and a report was submitted showing in each case the cause of the outbreak and the measures taken to deal with it. Anti-cholera inoculation was a novelty to the countryside and consequently only some 4,645 inoculations—mainly confined to contacts and those proceeding to an infected area—were performed. As small outbreaks continued to occur after the subsidence of the main epidemic, mainly in connection with small fairs, it was decided to prohibit by executive order the holding of fairs in infected or recently infected localities. Finally, as a means of checking the re-introduction of infection from Kashmir, a medical inspection post and cholera camp was established, with the previous sanction of the Punjab Government, at

Kohala on the main road from Kashmir where the names and addresses of all persons coming from Kashmir were taken for transmission to the medical authorities at the destination of the traveller. The post, in spite of the restricted nature of its functions, fulfilled a decidedly useful function but, owing to the decline of cholera in Kashmir at the end of July, it was closed on August 1st, 1925.

(4) *Summary.*—This small epidemic of cholera is noteworthy by reason of the fact that it exhibited certain epidemiological features of great interest.

In the first place the appearance of cholera in epidemic form in the month of April instead of in the "normal" season (July-September) being without precedent during the past 30 years, was highly abnormal.

Secondly, the spread of infection from the north instead of from the endemic area in the United Provinces was likewise a most exceptional feature.

Thirdly, contrary to custom, the epidemic involved Muhammadans in its early stages instead of Hindus.

Finally, the decline of the epidemic took place at the height of what has hitherto been regarded as the "normal" cholera season.

The first three features would all appear to be referable to the fact that cholera, contrary to custom, prevailed throughout the winter in Kashmir—95 per cent. of whose inhabitants are Muhammadans—whence it is assumed to have spread early in the year to the adjoining district of Jhelum in the Punjab. The early decline of the epidemic—assisted no doubt by action taken to combat it—would appear to suggest that the epidemics of cholera exhibit a somewhat labile seasonal periodicity in this Province. Indeed, it is noteworthy that in several of the Sanitary Reports of this Province of over 30 to 60 years ago, it is stated that cholera epidemics that start in April may be expected to end in August, whereas those starting in June and July are likely to continue until October and November. It is appropriate here to pay a small tribute to the memory of Bryden, Cunningham and more especially of Bellew—a whilom Sanitary Commissioner of the Punjab—by stating that the accuracy of many of the epidemiological observations made by them at a time when our ignorance of the ætiology of epidemic diseases was profound, is a constant source of admiration.

(5) *Conclusion.*—A study of the Punjab Sanitary Reports and of Bellew's *History of Cholera* brings to light certain facts which suggest that this relatively unimportant outbreak may represent an incident in the history of cholera of considerable importance.

It indeed appears that at irregular periods which usually recur about once in every twenty or so years, cholera, after exhibiting unusual

prevalence in its endemic home, assumes enhanced powers of diffusion and toxicity as the result of which it spreads along "the northern epidemic highway" of Bryden not only to the Punjab but also to Kashmir and thence to Central Asia and to Europe. Eight so-called pandemics of cholera are thus recorded to have occurred during the nineteenth century, the last of which, it may be noted, commenced in India in the year 1900 or 25 years ago.

On examining the local history of these pandemics, as recorded in the Punjab Sanitary Reports, it appears that each has been associated with an almost precisely similar sequence of events—viz. the abnormal prevalence of cholera in one year in the endemic home, the infection of Kashmir late in the same year, the *persistence of cholera in that country throughout the winter* and the extensive infection of the Punjab in the following spring. The history of cholera in Kashmir is not completely known, and it may be that cholera has exhibited this hibernal activity in Kashmir at other times, but it would appear that the marked persistence of cholera throughout the winter has been a distinctive feature in the history of the majority of the recorded pandemics. In these circumstances it is possible that recent events in Kashmir may represent the second stage of a new pandemic of cholera of which the severe epidemic in the endemic home of cholera in 1924 constituted the first stage.

In the light of this surmise the appearance of cholera in the Punjab in April 1925 may possess considerable significance, but whether this be so or not it is abundantly clear that a widespread infection of the Punjab in the spring markedly facilitates the introduction of cholera into Afghanistan and thence into Central Asia, for, if cholera should prevail in the Punjab during the spring, it will synchronise, as recently remarked by Fry, with the period when thousands of Afghans (*Powindahs*) are passing through the Punjab on their way back to Afghanistan. The occurrence of cholera in the Punjab in the spring instead of during the normal cholera season (July—October) is therefore likely to lead to the infection of Afghanistan on a large scale. That this migration (which is confined to the spring) actually led to the spread of infection to Afghanistan during the present spring, is borne witness to by a military staff officer stationed on the north-west frontier who informs me that he personally saw in May 1925 several caravans hastening in panic-stricken flight through the passes into Afghanistan leaving behind them uncontrovertible testimony (in the shape of a trail of cholera corpses) of the fact that cholera was exported into Afghanistan in the month of May 1925.

It seems, therefore, possible that the stage is set for an epidemic of cholera in Afghanistan and that in due time and season the repercussion of recent events in the Punjab will be felt in distant parts of Asia and even in Europe.

AN ACCOUNT OF AN OUTBREAK OF CHOLERA AT GOALUNDO GHAT.

By W. J. MARSHALL,

Supervising Medical Officer, Goalundo Ghat Hospital, Goalundo.

THE hospital, which I have the pleasure and privilege to serve in conjunction with Sub-Assistant Surgeon Amrita Lall Chanda, Medical Officer-in-Charge, has had what would appear to be a very unique experience. Between the 19th September, 1925, and 8th October, 1925, there were 24 admissions to hospital for cholera, all of whom recovered. I do not wish to imply by this that some new method of treatment has been devised which will still further reduce the mortality from this fell disease, but simply to bear humble testimony to the efficiency of the method of treatment by atropine, hypertonic saline and alkalies, introduced and advocated by Sir Leonard Rogers. In its application though we have been guilty of errors of omission and commission in that, in particular, the blood pressure and specific gravity of the blood are not recorded, we do not possess the necessary equipment for this purpose, nor is the temperature of the transfusion fluid adjusted to that of the patient. When cholera patients arrive in the midst of the ordinary routine work, professional and clerical, it is not always practicable to spare the time needed to follow the meticulous details devised by the author of the method and to do so requires whole time service and a specially trained staff. The most essential points in the treatment are to replace the fluid content of the blood and combat collapse. I cannot say that the present series of cases on the whole were any milder or less virulent than those in previous outbreaks to which reference will be made hereafter. At any rate I am prepared to own that good fortune attended our efforts in this particular instance.

Before dealing with the outbreak, a brief description of Goalundo may not be out of place. Goalundo, located on the river Padma below the confluence of the Ganges and Brahmaputra, is not a permanent station. Owing to the changes in the channels of the river the station frequently shifts several miles up and down stream according to where a connection can be made between the railway and river services. The place is 155 miles from Calcutta by rail and is the point at which a large number of passengers transfer to the various steamer services for the onward journey to Dacca, Mymensingh, Assam, Cachar, Sylhet,

admission was queried, pending a more detailed examination of her case. The child had not been anywhere away from Goalundo, the drinking water was obtained direct from the river which is the only source of supply to most of the inhabitants of these parts, and nothing but freshly prepared food had been eaten. Incidentally, with few exceptions the inhabitants of these parts are rice eaters. After the rice is cooked the pot is removed from the fire and a variable quantity of *cold* water, the nearest at hand and perhaps contaminated with the virus of cholera, is added. The liquid is drained off and the pot replaced near the fire to favour evaporation of moisture, assisting the process by occasional shaking. Would this be sufficient to destroy the virus and re-sterilize the rice? It was not till Case No. 2

was admitted that some clue was obtained as to the probable origin of the outbreak. During the 14th and 15th September, 1925, squally weather prevailed locally. A large number of fishing boats—light flat-bottomed craft manned by 2 to 6 or more fishermen—took refuge from the fury of the wind and waves in an area of shallow and almost stationary body of water marked "A" on the map, and bounded on three sides by the railway embankment, a raised footpath, and the

bazaar. It was ascertained that two and possibly more of those living on the boats during that time were attacked with profuse diarrhoea and vomiting. Instead of applying for relief at the hospital they sailed for home, an unknown destination. Such fishermen are not local inhabitants but visit this locality periodically during the fishing season. What their previous movements were, how long they had been here and whether they originally came from an infected area, presuming them to be cases of cholera, must now remain a mystery. The connection between those cases and the subsequent ones seems, however, to be fairly well established. From the outset the river water was strongly suspected of being the source of infection and the sequence of cases indicated on the map strongly supports that suspicion. The spread of infection through the agency of flies and infected particles of dust contaminating food supplies may safely be excluded on this occasion,—the former being conspicuously absent during the flood season—in view of the fact that every conceivable form of filth and rubbish in which they breed is consigned to the water, while such land as is above water is saturated with moisture and consequently there is no dust worth mentioning.

The area marked "No. 6 Bazar" in the sketch a few years ago formed the connection between the railway and river services when the river flowed in that direction. During the monsoon season there is still traffic between the railway and country boats. There is also a comparatively large bazaar and it is the home of many who carry on business or are employed in other ways at the ghats. My information is that the first reported case of cholera in this area occurred on the 28th September, 1925, as to whose movements, etc. nothing is known. Since then there have been 32 attacks and 20 reported deaths (21st October, 1925). It is fairly safe to infer that the outbreak there was not directly due to diffusion of polluted river water from the ghats where cholera was prevailing but through human agency. Case No. 21 was the only case admitted to hospital from this area.

Case No. 3 was the daughter of a railway employee living in quarters on the brink of the area of water marked "A" in the sketch. The railway colony is provided with tube and pucca wells. How then came this child to contract the disease, assuming the well water to be above suspicion? A visit to the quarter to investigate the case elicited the fact that the child often left the precincts of the house unknown to the parents. It was probably on such an occasion that feeling thirsty she drank of the water surrounding the quarters. In the house were found several receptacles containing water, some with clear and clean looking water said to have been drawn from the well, while others contained crude dirty water taken from near the quarters for cooking purposes; probably this also was drunk by the patient. In this case most of the places in and around the quarters known to have been fouled

by dejecta and vomited matter were promptly disinfected.

Diagnosis.—The diagnosis of cholera was made solely on clinical evidence. With the exception of a few patients cases who did not have all the characteristic signs and symptoms the remainder were admitted during the stage of collapse and presented the usual typical picture, viz.,—the initial diarrhoea of fluid faeces and vomiting of undigested food rapidly changing to copious motions and vomited matter "like water" as described by the patient, which subsequent inspection showed to consist of almost clear colourless fluid with a deposit of white flocculent or granular matter and accompanied by the usual concomitant signs and symptoms of that disease. Case 22 was the only doubtful case clinically. He gave a history of having obtained his water supply from the river and of frequent motions and vomit "like water" but on the day previous he had eaten stale rice and fish, his eyes and cheeks were sunken—the skin clammy, toes and finger tips shrivelled but his pulse was fair and subsequent inspection of his stools showed them to be not truly characteristic of cholera.

General routine procedure of treatment.—The quantities stated refer to adults, and for children to proportionately less. On admission atropine gr. 1|100 to 1|50, with digitalis 1|100 hypodermically—continued twice daily or oftener according to circumstances. An initial dose of calomel gr. iv. or v. combined with sodium bicarbonate, followed two hours later by $\frac{1}{2}$ gr. doses every half to one hour for 8 to 12 doses. The smaller doses are often continued on the day following admission, rarely longer. This is a rational procedure inasmuch as it assists in the elimination of the causal organisms and their toxins. Should the motions at the end of this time not show definite signs of improvement potassium permanganate pill grs. ii each are administered half-hourly or hourly for eight or twelve doses and repeated if the stools still do not improve. Hypertonic saline is given intravenously in quantities of three pints—occasionally 4 or 5. (Alkaline solution is given first when a history of complete suppression of urine is obtained.) After the first few ounces of saline have flowed into the vein, adrenalin solution (1 in 1,000) min. x to xv is added to the container—the barrel of a 4-oz. syringe. In second and subsequent transfusions one pint of the alkaline solution is given first followed by 2 pints of hypertonic saline with addition of adrenalin as before. Occasionally pituitrin, $\frac{1}{2}$ c.c. in very severe cases, is added.

In the present series none of the serious complications or sequelæ were present in a marked degree. In only one case was dry cupping resorted to and in ten others warm alkaline solution per rectum every two to four hours to assist in re-establishing the functions of the kidney.

The essential oils' treatment was tried in Cases 6, 7 and 17 with the results noted.

Patients on this and previous occasions complain of it as being too pungent and irritating.

Case 6, admitted at 8 a.m. in a condition short of collapse, was given atropine, digitalis and calomel as usual, then the essential oils mixture, a drachm every half hour for 5 or 6 doses. By 5 p.m. the patient was found collapsed, when hypertonic saline transfusion with small divided doses of calomel every hour for 6 doses was given.

Case 7, admitted 25-9-25, with cold and shrivelled extremities and perceptible pulse. Atropine and digitalis as usual. Essential oils' mixture as for No. 6. Urinary suppression followed. Dry cupping and warm alkaline solution per rectum. 26-9-25. Calomel gr. $\frac{1}{2}$ every hour for 12 doses, kaolin drink, cupping and alkaline transfusion per rectum repeated, followed by improvement.

Case 17, admitted 8-30 a.m. short of collapse. Essential oils' mixture every $\frac{1}{2}$ hour which he could not retain. Started on permanganate pills at 12 noon 1 every $\frac{1}{2}$ hour. On the second day no change in the character of the stools, pills continued. On the 3rd day motions liquid and containing bile. By 10-30 a.m. was collapsed. Saline transfusion, etc., and pills continued, tardy convalescence.

* Principally famine-stricken tea-garden coolies.

For such gratifying results, in the absence of good conditions and nursing, in its true sense, the credit is due in particular to Sub-Assistant Surgeon Amrita Lal Chanda, the Medical Officer-in-Charge, on whom the brunt of the work fell, and to the staff generally for their valuable assistance.

Cholera outbreak at Goalundo 19th September, 1925 to 8th October, 1925.

ADMISSIONS FOR CHOLERA.

Serial Number.	Date of Admission.	Occupation.	Age.	Sex.	Caste.	No. of saline transfusions.	Result.
1	19-9-25	D/O Dry Store Vendor	5	F, ch.	H	1	Recovered.
2	22-9-25	Fisherman	24	M	H	1	Do.
3	22-9-25	D/O Railway employee	6	F, ch.	H	1	Do.
4	23-9-25	Boatman	42	M	M	1	Do.
5	25-9-25	Fisherman	20	M	H	1	Do.
6	25-9-25	Fisherman	40	M	H	1	Do.
7	25-9-25	Sweetmeat Vendor	30	M	M	Nil	Do.
8	26-9-25	Do	44	M	H	1	Do.
9	28-9-25	Railway Employee	45	M	M	2	Do.
10	Do.	Fish Nikari	22	M	H	1	Do.
11	Do.	Steamer Co. employee	25	M	M	2	Do.
12	Do.	Fisherman	26	M	H	1	Do.
13	29-9-25	Fisherman	45	M	H	1	Do.

16	Do.	Steamer Co. employee	55	M	M	2	Do.
17	Do.	Bird & Co.'s employee	45	M	H	1	Do.
18	Do.	Fisherman	26	M	H	1	Do.
19	2-10-25	Bird & Co.'s employee	25	M	H	2	Do.
20	3-10-25	Cultivator	30	M	H	2	Do.
21	4-10-25	Cooly from Jute Press	45	M	M	1	Do.
22	5-10-25	Cultivator	35	M	H	Nil	Do.
23	6-10-25	D/O Cultivator	9	M, ch.	H	Nil	Do.
24	8-10-25	W/O Steamer Co. (3 months employee pregnant-aborted, 16th October, 1925.)	35	F	H	2	Do.

The symptomatic treatment need not be referred to.—nothing but plain water, coconut water, kaolin drink (1 in 4) is allowed until the motions assume their normal character, and then barley water, whey, thin sago, soft rice with *ghole* and *dahi* onwards to normal diet.

COMPARISON WITH PREVIOUS YEARS.

As I have been associated with this institution for a year and a half (1914-15) and again from April 1919 to date and so also has Dr. Chanda since 1917, it occurred to me to compare collectively results with previous years and these are set out in the following table:—

THE OCCURRENCE OF URTICARIA IN THE TREATMENT OF MALARIA BY QUININE.

By Major T. A. HUGHES, M.A., M.D., D.P.H. (Dubl.),
M.R.C.P. (Lond.),

King Edward Medical College, Lahore.

CUTANEOUS eruptions, usually of an erythematous, scarlatina-form or urticarial nature, are among the toxic effects produced by quinine in certain people, and although they may occur without any other symptoms of cinchonism they interfere with the efficient treatment of malaria in such subjects. This is especially the case with urticaria, where itching may be so severe as to

be almost unbearable. On the other hand malaria may be the cause of an urticarial rash which appears with each paroxysm, or in periodic outbursts when the disease is latent or its clinical features not characteristic. Here the administration of quinine will usually clear up the skin condition along with the other manifestations of malarial infection, although in some cases the cutaneous eruption is aggravated by each dose of the drug. In some of these cases it is probable that quinine by itself would produce urticaria, while in others the malarial infection has sensitised the skin to the action of quinine.

Lewis and Grant (1924), as a result of observations on the cause of factitious urticaria and the wheals produced by burning, conclude that there is in the skin "a single and organised mechanism of defence against injuries of all kinds." This consists of (a) a local primary dilatation of the minute skin vessels independent of arteriolar dilatation and of the nervous system; (b) a surrounding flush due to widespread dilatation of the arterioles of the skin and dependent on a local nervous reflex; and (c) an output of fluid into the tissues due to increased permeability of the vessel walls and not controlled by nervous influence. The agent setting this mechanism in motion is a chemical substance with a histamine-like action derived from the skin, and it is possible that certain drugs which produce urticarial eruptions act in a similar manner. That an excitable nervous system is also a factor in some urticarias is seen from the fact that an outbreak of wheals occurs as a result of nervous excitement in some people and has been recorded in exophthalmic goitre and the lightning pains of tabes. An urticarial eruption could also be produced by stimulation of such a nervous system by drugs. The classification of drug eruptions given by Jonathan Hutchinson (1911) follows these lines. He divides drug rashes into (1) those that result from direct action of the drug on the skin by absorption from outside, (2) those that are due to the direct action of drugs carried to the skin in the blood, and (3) those that are probably produced through the central nervous or vasomotor system. The eruptions in class (3) are usually erythemas or urticarias or combinations of these and are mainly symmetrical. Quinine rashes would seem to belong mostly to the last class. Two cases are here recorded in one of which quinine, given in the treatment of malaria, produced a marked urticarial eruption all over the body, while in the other it aggravated a generalised urticaria already existing as a result of a malarial attack.

Case 1.—Miss G., a nurse in the Mayo Hospital, was warded with a history of rigor and a rise of temperature to 100.6° . The spleen was enlarged $\frac{1}{2}$ inch below the costal margin, all other organs being apparently normal. Malarial parasites were not found in a thin blood film, but the clinical history and symptoms pointed to malaria. The patient stated that she had

never had malaria before and that she had never taken quinine. The nervous temperament did not seem to be in any way abnormal. On admission the usual purgative was given followed by "quinine and alkali" mixture (Sinton 1923; 1923a), ten grains of quinine being given on the first occasion. This was followed, in about 20 minutes, by a generalised urticarial rash with intense itching, the wheals varying from $\frac{1}{4}$ to $\frac{1}{2}$ inch in diameter. The face was swollen and the eyes congested and watery. The patient also complained of an itching sensation in the mouth, pharynx, and eyes, as well as frontal headache and buzzing in the ears. There was no dimness of vision and no deafness. These symptoms lasted for two hours when they completely disappeared. The temperature came down to normal. The dose of quinine was then cut down to five grains, but urticaria, etc., resulted as before after each dose. The rash was not alleviated or prevented by bromides or calcium lactate. The temperature remained normal or sub-normal except for a rise to 100.6° on the evening of the second day. On the third day quinine was given in three five-grain doses and 5 minims of adrenalin hydrochloride (1 in 1,000) were injected hypodermically about 5 minutes after each dose. Slight buzzing in the head was complained of, but there was no rash, no itching, and no headache. On succeeding days the same treatment was continued but the quinine was gradually increased to ten grains thrice daily. No untoward symptoms appeared. The patient was discharged to duty on the 7th day, having been free from fever for 6 days and from urticaria for 4 days. The spleen had diminished in size. The patient was not menstruating during her illness. On the 8th it was found that urticaria did not follow the ingestion of ten-grain doses of quinine even when adrenalin was omitted, the susceptibility of the skin to that drug having disappeared. Slight shakiness was noticed after each injection of adrenalin.

Case 2.—Patient (Miss H.), aged 51, was admitted with a generalised urticarial rash which was very irritable. There was a history of chronic malaria and dysentery, and the rash was said to appear with the onset of any acute illness and to be aggravated by quinine. The spleen was two inches below the costal margin. Other organs were healthy, there being no symptoms of dysentery and no pyrexia. The blood showed numerous subtertian rings. No pathogenic entamoebæ or cysts were found in the stools. The patient remained in hospital 4 days, on the second of which she had a slight rigor with a rise of temperature to 100.8° , the fever lasting a couple of hours. Defervescence occurred with sweating. On admission the usual antimalarial treatment was started, but after the first dose (ten grains) of quinine the rash became much worse. Sweating also aggravated the rash. Adrenalin administered as before did not benefit the skin condition but prevented its aggravation

by quinine. On the other hand calcium lactate in 30-grain doses seemed to bring relief but bromides were without effect. The rash disappeared on the fourth day after admission and the patient left hospital.

Experiments on the effects of quinine on the sugar concentration of the blood (Hughes 1925) showed that this drug in antimalarial doses in man usually caused a fall in the blood sugar, and that hypoglycæmia is often produced in rabbits by toxic doses when sympathetic glycolysis is prevented by ergotoxine. Evidence was adduced which indicated that this effect is due to increased liberation of insulin. Clarke (1924) demonstrated that parasympathetic stimulants produced a fall of blood sugar in rabbits, and his results suggested that this was the result of increased secretion of insulin brought about by stimulation of the vagus. The hypoglycæmic effect of quinine may similarly be due to parasympathetic (vagal) stimulation. From the fact that in the cases here recorded the effect of quinine on the skin was abolished by a sympathetic stimulant, it is concluded that this drug also produces urticaria by parasympathetic stimulation. In both cases the skin vessels seemed to have been sensitised to the action of quinine by the toxin of malaria. This by itself in the second case produced an eruption which was not affected by adrenalin and which, therefore, was most likely due to direct action on the vessel walls.

NOTES ON MALARIA IN THE AGENCY TRACTS, MADRAS PRESIDENCY.

By J. DHAIRYAM, I.M.S.,
 Wellington, Nilgiris.

THE Agency Tracts of the Madras Presidency are hilly regions mostly below 4,000 feet above sea-level, with a very cold winter, a very hot summer, and a rainy season accompanied by extremely heavy downpours of rain; in fact the climate as a whole is one of extremes. Swampy areas and waterlogging are very common, whilst the hilly region in general is covered with forest and thick vegetation. When the subsoil water-level rises at the end of the rains, the fever season sets in and persists throughout the winter.

The majority of the population perhaps are afflicted with malaria, though the disease is not usually of a severe character, and during the hot weather cases are fewest in number and mildest in type. In the Jeypore Agency in Vizagapatam District, however, I have come

across fatal cases of cerebral type. Such cases shew an onset with constipation, followed by chill and fever, usually between 10 A.M. and 12 noon. The patient loses consciousness; the body, at first warm, becomes cold and the pulse more and more feeble. The rectal temperature, however, remains high.

At first I treated such cases by intramuscular injections of quinine, at a dose of 10 grains a day. Later intravenous injections of quinine were tried, but in severe cases these appeared to increase collapse. I finally resorted, therefore, to intramuscular injections of quinine, given two or three times daily. An illustrative case may be cited:—

The patient was a Malabar police constable engaged on active military service against rebels in the Agency Tracts in 1923. He first had a severe attack of malaria with a temperature of 105°F. After oral treatment he appeared to be doing well and to be recovering. A week later, on going to get water to drink from the kitchen, he was found unconscious on the floor, tossing about and groaning. The sub-assistant surgeon in charge, not having previously seen such a case, took it to be one of cerebral hæmorrhage and treated the patient accordingly. The attack occurred about 11 a.m. and the patient was brought down to the Base Hospital by ambulance car and admitted about 1 a.m. that night. He was then almost unconscious, groaning, and restless, with a rectal temperature of 104.5°F, the body cold and clammy, the pulse 56 per minute, of feeble and flickering tension. Typically—in other words—a case of cerebral malaria.

I started with heart stimulants, enemata, croton oil by the mouth and an injection of 10 grains of quinine intramuscularly. Three hours later the patient had passed some motions in bed, but the condition was otherwise the same. Four hours later a second intramuscular injection of quinine was given. Mustard plasters were applied to the nape of the neck and to the calves. Lumbar puncture was carried out and a little fluid withdrawn. Three further intramuscular injections of quinine were given at four hourly intervals. The treatment given aimed at (a) killing off the malarial parasites; and (b) reducing the cerebral congestion. He was convalescent within two days and recovered completely.

Certain miscellaneous observations with regard to malaria in this district may be of interest. In general, women in this district appear to suffer less from malaria than do the men. Further there is a settled conviction among the male inhabitants of the district that to take quinine leads to sexual impotence; one patient having informed me that he actually used quinine injections to suppress sexual desire. As malarial fever, however, is far more likely to lead to sexual impotence than quinine administration, the latter is the lesser of two evils.

The women in the Agency Tracts are generally clothed in a saffron coloured garment and wear yellow *sarees*. It is known that mosquitoes are attracted by black clothing and repelled by yellow clothing; possibly the clothing of the women in saffron yellow may have something to do with their relative immunity from malaria as compared with the other sex.

A belief is prevalent in the locality that cooked onions, taken before each meal, confer a certain amount of freedom from fever on those who eat them. The amount to be taken is about half a

dozen onions a day. Lemon juice beverage is also said to be useful as a prophylactic. Bachelors and married men living apart from their wives and families also appear to be less susceptible to malaria than do married men residing with their families. A daily walk of 8 or 10 miles is held to be a useful precautionary measure locally against infection with malaria.

ON A SPECIES OF *TRICHOMONAS* PREVALENT IN CALCUTTA.

By BIRAJ MOHAN DAS GUPTA, L.M.P.,

Temporary Assistant Surgeon, Assistant Professor of Protozoology, Calcutta School of Tropical Medicine.

THE question of the number of species of the genus *Trichomonas* parasitic in the intestine of man may seem to be an academic one, yet it is in reality not so, as its solution may possibly be intimately related to the pathogenicity or non-pathogenicity of this parasite to man.

The type species of the genus of flagellate protozoon, *Trichomonas*, is *Trichomonas vaginalis* Donné, 1837, stated by Reuling (1921) upon a careful study of it to possess four anterior flagella arising from the anterior pole and passing forward. Davaine in 1854 was apparently the first person to see *Trichomonas hominis*, the intestinal *Trichomonas* of man, in the stools of a patient suffering from typhoid fever. He correctly described its undulating membrane and the postero-lateral projection from the body of the parasite of the terminal free portion of its trailing, posterior flagellum. In 1860 he gave a drawing of the parasite, reproduced by Kofoid (1920), but shewing only one anterior and one posterior flagellum. He applied to it the name *Cercomonas hominis* (variety B). Lambl (1860) re-discovered *Trichomonas hominis* in its dying and pseudo-amœboid phase in stale stools, but mistook it for an amœba,—a mistake which has been not infrequently repeated in the literature, notably by Castellani in his description of dying *Trichomonas* as *Loëschia undulans* Castellani, 1905.

It is a little difficult at this date and with the literature at my disposal to discover who first pictured *Trichomonas hominis* as a flagellate protozoon possessing a group of three anterior flagella arising from one or more basal granules at its anterior pole, and a separate posterior or trailing flagellum, anchored to the body of the parasite by an undulating membrane. Leuckart (1879) gave a description of the parasite to which I have not had access. Doflein (1916) is very cautious as to the number of anterior flagella possessed by the parasite; he regards three as typical; but considers that individuals may be encountered with four anterior flagella, the fourth possibly derived from the trailing, posterior flagellum by detachment from its undulating membrane. Wenyon and O'Connor (1917), working at Alexandria during the War, are more definite; they state that three, four or five flagella

may be seen to arise from the anterior pole of the parasite and to pass forward, but that four flagella is the most common finding. (To a considerable extent the intertwining of the group of flagella so arising from the anterior pole may be responsible for many mistakes, and render the exact number of anterior flagella difficult to count.)

Dobell—(Dobell and O'Connor, 1921 p. 68, footnote)—is far more definite upon the subject. Working at Hampstead during the War, upon an almost unlimited supply of material, he concludes that the commonest variety encountered had four anterior flagella, but that individuals with three and five anterior flagella are not infrequently to be encountered. He concludes that the contentions of other workers that three different genera or sub-genera, *Tritrichomonas*, *Tetratrichomonas*—or *Trichomonas, sensu strictu*, since it conforms to the type species, *T. vaginalis*,—and *Pentatrichomonas* should be established for different races having respectively three, four or five anterior flagella (in addition to the posterior, trailing flagellum of the undulating membrane) are unnecessary; such individuals appear to be merely variants from the type species.

Despite the very great weight of Professor Dobell's authority, the matter does not appear to be as simple as it sounds. The number, disposition and specialisation in function, etc., of their different flagella have been made the basis for the generic classification and differentiation of the Polymastigina, and accordingly Kofoid (1920) reserves the genus *Trichomonas* for the variety of parasite with four anterior flagella. As this leaves the variety with three anterior flagella unnamed, he proposes the generic name *Tritrichomonas* for it.

With regard to the genera,—sub-genera, variants or whatever they are—which possess three and four anterior flagella respectively, no claims for pathogenicity worth considering have yet been put forward. With regard to the penta-flagellate type, with five anterior flagella, the case is different.

Attention to the genus—(sub-genus, species or variant)—*Pentatrichomonas* was first drawn by Derrien and Raynaud in 1914. They found it in considerable numbers in the stools in a severe case of dysentery; the infection appeared to resist all forms of medication from December 1st, 1913, till February 1st, 1914, but was then apparently cured by the combined oral and rectal use of turpentine; it is stated that no other parasites were found in the stools. A short but clear description of the parasite is given, and 5 anterior flagella are described of length 10 to 17 μ . They proposed for the parasite the name *Hexamitus ardin delteilii*. Mesnil (1914, 1915), however, shewed that *Hexamitus* was already pre-occupied, and proposed *Pentatrichomonas ardin delteilii* (Derrien and Raynaud), 1914.

Chatterji (1915) discovered the same parasite in the stools of a patient with chronic dysentery

in Calcutta, and published his description of it independently before Derrieu and Raynaud's paper was brought to his notice. Recurring to the same subject in 1917, he records 32 cases of chronic dysentery in Bengal in which he considered *Pentatrachomonas* pathogenic, and notes that he had not found true *Trichomonas*—presumably meaning the tetra-flagellate form—in Calcutta.

Subsequent to the appearance of the papers by Derrieu and Raynaud and by Chatterji, a considerable number of observers have claimed pathogenicity for *Pentatrachomonas*, notably Haughwout (1918, 1919, 1920), who reports on its prevalence in Manila, and on its ingestion of red blood corpuscles.

Wenyon and O'Connor (1917, p. 79) remark with regard to their observations in Alexandria during the War, "the commonest type seen by us has been *Tetratrachomonas*, though three-flagellar and five-flagellar forms have been seen, each on one occasion." They are clearly of opinion that *Trichomonas* is not pathogenic; "it is illogical to call such cases *Trichomonas* diarrhoea, while there is no excuse whatever for the use of the term *Trichomonas* dysentery. The cases of dysentery in which *Trichomonas* has been present have been cases of bacillary dysentery."

Dobell—(Dobell and O'Connor 1921, p. 68, footnote)—remarks "I regard these so-called sub-genera rather as varieties." In a critical review of the literature, he regards the evidence in favour of the pathogenicity of *Trichomonas* as highly unconvincing; the fact that it ingests red blood corpuscles when presented to it is not evidence of its tissue-invading properties, and the strongest evidence in favour of its pathogenicity is the post-mortem finding by Wenyon (1920) of *Trichomonas* in the lumen of the glands of Lieberkühn, with ruptures of the gland epithelium, and trichomonads scattered in the inter-glandular loose connective tissue. Wenyon notes, however, that the trichomonads were distributed regularly through the tissue, that there was no cell or tissue reaction; and he considers that the trichomonads had penetrated the gut epithelium only shortly before the death of the patient. He concludes "The present paper shows that *Trichomonas* may invade the tissues of the intestine, but whether this is evidence of its pathogenicity or not, future work alone will show. So little is known at present that any expression of opinion would be merely valueless guess work."

That *Trichomonas* may occasionally pass from the lumen of the gut of a living animal into its blood stream was shown by Chatton (1920) who succeeded in obtaining a culture of it from the blood of a gecko which had an intestinal infection with the same flagellate.

Writing on the nomenclature of the human intestinal flagellates in 1920, Kofoed mentions only *Tritrachimonas*, and *Trichomonas* with four anterior flagella. In 1923, however, Kofoed and

Swezy reported three cases of infection with *Pentatrachomonas* in man, in which they considered the flagellate to have been pathogenic. "In our experience," they write "the common trichomonads of the human intestine, urogenital tract, and mouth all have four anterior free flagella. In case only three are seen at first, a fourth can be found if the material is so prepared as to be adequately examined. In our experience failure to find the fourth has been due to the belief that three is the normal number, or to inexperience in analysis of specimens, or to the disadvantageous position of one of the four flagella, as, for example, when it is hidden under the body. Fundamentally, the reason lies in a failure to observe the differential behaviour of one of the anterior flagella." They describe the five free anterior flagella as distributed into two groups; four arise together from a distal basal granule and beat together at a slow rate. These may easily be mistaken for only one, two or three flagella unless carefully observed, as their movement is synchronous and they tend to intertwine. The fifth flagellum arises from a different basal granule, passes forward and laterally, quite independent from the other grouped four, and beats with a much faster and independent rhythm. Finally the sixth, or posterior trailing flagellum, passes backwards along the margin of the undulating membrane. It is essentially by the different behaviour of the two groups of flagella that *Pentatrachomonas* is differentiated by these authors as a separate genus; but it appears to be more resistant than *Tritrachimonas* and *Trichomonas*, *sensu strictu*. It ingests red blood corpuscles, resists emetine preparations and arsenical drugs, survives in liquid stools for 24 days, in tap water for 3 days and in normal saline for 13 days. No cysts have been observed, and the parasite is readily cultured in 10 per cent. rabbit serum in Locke's solution both at room and body temperatures. In the three patients in whom Kofoed and Swezy encountered *Pentatrachomonas* infection they consider that there is full evidence that the parasite caused an intractable diarrhoea; and they further believe that epidemic infections with this parasite may occur when drinking water is infected, as reported by Escomel (1919).

EXPERIMENTAL WORK.

Such being the position, it is obvious that much further work upon the trichomonad parasites of man is wanted, and during the past year special attention has been paid to these parasites in Calcutta.

During these six months *Trichomonas* infection has been encountered in 12 diarrhoeic stools, 7 semi-fluid stools, and 4 more or less formed stools; or in all 23 times. On each of these occasions a positive culture of *Trichomonas* was obtained from the stool and the cultures were examined in the fresh state, by dark ground illumination, and in stained preparations, using

osmic acid fixed, Giemsa stained films, and fixation by Schaudinn's fluid, followed by iron hæmatoxylin staining.

In every one of these 23 instances the parasite encountered has conformed to Kofoid and Swezy's description of *Pentatrichomonas*. It has five free anterior flagella, four of which are clustered together and beat with a rhythm different from that of the fifth, anterior free flagellum. Since commencing these observations and counting the flagella with care and accuracy I have not once encountered the types with three and with four anterior flagella.

This observation would seem to confirm that by Chatterji (1917) that the prevalent type of *Trichomonas* infection in Calcutta is with *Pentatrichomonas*.

With regard to the pathogenicity or otherwise of *Pentatrichomonas*, at present nothing definite can be said. It would be a mistake to make any assertions upon scanty material. The parasite has been seen to ingest red blood corpuscles, both in freshly passed dysenteric stools, and in cultures. In 5 of the 23 stools—(all dysenteric)—vegetative *Entamoeba histolytica* was present; these cases were undoubted cases of amebic dysentery, and yielded to emetine therapy. Further, in previous years I have frequently seen motile *Trichomonas* in the stools from cases of bacillary dysentery—as proved to be such by culture;—in fact one had come to regard it as a common finding in bacillary dysentery, where the alkaline character of the stool and its richly nutritious content would provide excellent pabulum for the parasite. Before any claim to the pathogenicity of *Pentatrichomonas* can be verified, it will be necessary to have sets of observations extending over a large number of patients and a long period of time, in which repeated examinations have been made to exclude the possibility of infection with *E. histolytica*, and repeated cultures taken to exclude the bacillary causes of diarrhoea and dysentery. To find a parasite in a dysenteric stool is not evidence that the parasite is the cause of the dysentery. There are such things as Koch's postulates, although many workers seem to ignore them. On the other hand the careful work of Kofoid merits serious attention, and further and systematic investigation is called for.

In none of the human trichomonads has any encysted form so far been discovered. The cyst of *T. batrachorum* of frogs has been described by Dobell (1909), and that of *T. caviae* of the guinea-pig by Brug (1917); but all the earlier descriptions of cysts of human *Trichomonas*, as Dobell remarks, and as the figures in different protozoological atlases clearly shew, are really figures of *Blastocystis* or of *Chilomastix* cysts. *Blastocystis hominis*, it may be remarked, is a serious drawback in all cultural work with *Trichomonas*; if present, it will overgrow a *Trichomonas* culture in a couple of days and kill off or starve out all the flagellates.

It was thought that placing the parasite under conditions of adverse environment in culture might cause it to encyst. Luxuriant cultures were obtained by inoculating tubes of Row's culture medium for *Leishmania* with portions of mucoid stool rich in *Trichomonas*. (To prepare Row's medium 10 c.c. of rabbit or human blood is taken, defibrinated, and added to 90 c.c. of distilled water to lake the blood. One volume of this laked blood solution is added to 2 volumes of sterile 1.2 per cent. saline). On incubation at 37°C., rich cultures of *Trichomonas* are obtained, with either rabbit or human blood.

(a) One such culture was placed in a desiccator at 37°C. and observed daily for 3 days. The flagellates remained motile and active.

(b) A second culture was transferred from 37°C. to the 22°C. incubator.

(c) A third culture was transferred from the 37°C. incubator to the refrigerator chamber at freezing point.

In (b) and (c), observed daily, no motile flagellate was found after the first 24 hours; they all appeared to have died and many of them were disintegrated. In none of (a), (b) and (c) were any encysted forms encountered. Further, whereas a temperature of 22°C. appears to be rapidly fatal to the parasite, one culture strain survived for 63 days at 37°C. on subculturing every third day in Row's medium.

It is suggested by Kofoid and Swezy (1924) that possibly *Pentatrichomonas* infection may pass from man to man in its motile phase, and not through the channel of encystment at all; that its long period of survival in tap water, (3 days), or in passed stools, (5 to 24 days), may carry the flagellate in its motile phase *via* contaminated water, etc.; from man to man. Hitherto it has generally been held that infections with the intestinal protozoa pass from man to man by the "contaminative cycle of Minchin," the cysts in passed faeces constituting the channel of infection, and being the forms in which these parasites are enabled to tide over their period of sojourn in the adverse environment outside the body. Kofoid's view of the possible direct infectivity of the motile, vegetative phase is therefore somewhat revolutionary. Nevertheless it merits attention, for many years' investigation of *Trichomonas hominis* by many different workers have failed to reveal its cyst.

EXPERIMENTAL INFECTION OF KITTENS.

To test the validity of this view "clean" laboratory animals or human volunteers are necessary, i.e., such as have shewn on repeated examination of their stools no infection with natural intestinal protozoa, or at least from whom it is reasonably certain that natural *Trichomonas* infections are absent. Such "clean" animals are very difficult to obtain, since very numerous species of animals are parasitized with *Trichomonas*. Kessel (1923) has described a method

of freeing rats of their natural intestinal entamœbæ and obtaining "clean" animals; 128 rats were caged and fed for two days on bread soaked in a saturated solution of magnesium sulphate. Their stools were examined on the first and second days after these feeds; they were then killed and the whole of the intestinal tract examined. In only 4 were entamœbæ detected at the post-mortem examination where the previous two examinations had failed to shew entamœbæ in the stools. From the table published in Kessel's paper, however, the method appears to be less successful in flagellate infections, and, in any case, one doubts whether the method is a completely reliable one for this purpose. If two days of drastic treatment with magnesium sulphate will clear the intestine of an animal of all contained entamœbæ, the method should afford the easiest way also of ridding man of entamœbic infections.

The handiest animals available being kittens, these were selected. It is almost impossible to get an animal species in which natural *Trichomonas* infections are known not to occur, and Wenyon and O'Connor (1917) note the occurrence of natural *Trichomonas* infections in cats in Alexandria. On the other hand, during the course of several years of examination of kittens' stools in Calcutta such a natural infection of kittens has only very rarely been encountered; the commonest intestinal protozoa in kittens appear to be *Coccidia*; entamœbæ and flagellate protozoa being very rare or almost completely absent.

Six kittens were selected and kept on a milk diet for three days, their fæces being examined daily. Two shewed coccidial infection, but the other four shewed no protozoal infections. As, however, I have sometimes noticed in the case of rats that no protozoa may be encountered in the stools, although there may be a heavy infection in the cæcum two kittens—(Nos. 1 and 2)—were killed, as controls, and the contents of their cæca thoroughly searched. No protozoa were found. Thus it appeared to be reasonably probable that the other four kittens were free from natural *Trichomonas* infection, or that such infection, if present, would only be present in scanty numbers.

To kittens Nos. 3, 4, 5 and 6 in each instance 30 c.c. of a very rich culture of human *Pentatrachomonas* was fed. Two of these kittens took this culture in milk voluntarily; in the other two it had to be administered by a stomach tube.

Kitten No. 3 was chloroformed 20 minutes after the feed, and the contents of its intestine examined at different levels, and cultures taken. Very active and very numerous *Pentatrachomonas* were found swarming in the stomach and a few about 5 cms. below the pylorus, but none at a lower level.

Kitten No. 4 was chloroformed 45 minutes after the feed. Numerous and very active

Pentatrachomonas were found about 21 cms. below the pylorus and 48 cms. above the cæcum, but none in the cæcum or rectum.

Kitten No. 5 was chloroformed three hours after the feed. Its cæcum was found to contain very numerous and active *Pentatrachomonas*, but there was no infection in other portions of the gut. The infection in fact appeared to have become especially localised in the cæcum.

In all three animals cultures were taken from those parts of the intestine which were found to be positive at examination; and in each instance a luxuriant growth of *Pentatrachomonas* was obtained, identical in morphology with those of the original strain. The parasites appeared to have retained full vitality as shewn by their staining reactions, movements, and growth on culture, and not to have deteriorated at all in transit through the gut.

After being fed on 30 c.c. of a similar culture, kitten No. 6 was kept as a control; its fæces being examined daily. For a month no protozoa were found in its stools. It then suddenly developed dysentery, and its stools shewed numerous coccidial oocysts, and scanty *Trichomonas*. On culture this material again yielded a good growth of typical *Pentatrachomonas*. After passing through this attack of dysentery, the kitten recovered, and is now—a month later—in good health, whilst no protozoa can be detected on examining its stools.

As a still further control to these experiments, it was decided to feed kittens with a coprozoic flagellate. As Dobell and O'Connor (1921) point out, such flagellate protozoa as *Bodo* may not infrequently be met with in the examination of human fæces. They are not true parasites of the human intestine, however, but accidental visitors either to the gut or to the bedpan; having a special affinity for a fæcal environment, and being coprozoic in habit.

A rich culture of a strain of *Bodo* isolated from the stools of a cholera patient having been obtained, to each of kittens Nos. 7 and 8 fifty c.c. of this culture was administered by the stomach tube. Kitten No. 7 was killed one hour later, No. 8 was killed one and a half hours later. Their intestinal contents were searched. In the case of No. 7 a very few motile *Bodo* were still present in the stomach, but none were seen elsewhere; in the case of No. 8 no protozoa could be detected at any level. Cultures taken for *Bodo* from the stomach, duodenum, jejunum, ileum and cæcum of both kittens yielded entirely negative results.

Thus it will be seen that in the case of *Pentatrachomonas*—a true parasite of the human intestine—the experiments shewed that actively motile and viable trichomonads passed unchanged through the whole length of the gut, settled in the cæcum, and appeared to establish a localised infection therein. In the case of *Bodo*—a coprozoic flagellate for man, and not a true

ant of the human intestine—the flagellates were destroyed in the gut.

CONCLUSIONS.

Whilst much further investigation is called for, it seems to me permissible to draw the following conclusions:—

1. The prevalent type—(or genus or sub-genus)—of human intestinal trichomonad in Calcutta is *Pentatrichomonas ardin delteili* (Derrieu and Raynaud), 1914. This confirms a previous similar finding by Chatterji (1917); and, if read in conjunction with the findings of other workers of recent years, appears to afford evidence that *Pentatrichomonas* is a parasite with a tropical distribution, whereas *Trichomonas*, *sensu strictu*, is a parasite rather of temperate zones.

2. As to its pathogenicity or non-pathogenicity to man, nothing definite can yet be said.

3. It can be readily cultivated in Row's hæmoglobin-saline medium at 37°C.; at 22°C. and lower temperatures cultures die out within 24 hours. A strain has been kept alive in Row's medium by sub-passage every third day for 63 days.

4. When rich cultures of this parasite are fed to kittens, viable flagellates pass unchanged through the stomach and intestine and settle in the cæcum, where they appear to be able to establish a localised infection. The test for the viability of these forms was by culture.

5. This appears to confirm Kofoid's suggestion that *Pentatrichomonas* infection in man may be acquired,—not by swallowing cysts, since the cumulative work of many investigators has failed to discover such cysts,—but by ingestion of the flagellate in its motile and vegetative form.

6. The behaviour of *Bodo*—which is not a true parasite of the human intestine, but a coprozoic flagellate,—in kittens is entirely different; it appears to be rapidly destroyed in the gut.

My thanks are due to Dr. Asa C. Chandler, Calcutta School of Tropical Medicine for suggestions and advice in this investigation; also to Major R. Knowles, I.M.S., Calcutta School of Tropical Medicine, for going through and examining my specimens on his return from leave, and for help in the composition of this paper.

SOIL ACIDITY AND SURVIVAL OF HOOKWORM LARVÆ. A CRITICAL COMMENTARY.

By Dr. L. FABIAN HIRST, M.D. (Lond.),
 City Microbiologist, Colombo.

AN article in a recent issue of this journal by Dr. A. C. Chandler on soil acidity and survival of hookworm larvæ begins as follows: "It is a prevalent opinion that acidity in soil has a tendency to shorten the life of infective hookworm larvæ. Hirst (1924), for instance, says "a markedly acid reaction is also most unfavourable to the continued survival of hookworm larvæ" and remarks that the most favourable pH reaction for the development of the larvæ in cultures from faeces requires investigation."

Dr. Chandler assumes, in my humble opinion quite unjustifiably, that soil acid exerts its main effect in the infective stage of the life history of the larva. His whole investigation is based on this erroneous assumption.

As far as I know, no competent authority has hitherto suggested that the degree of acidity ordinarily met with in soil has any marked effect on hookworm larvæ, once they have developed to the infective stage.

There are two stages in the development of hookworm larvæ outside the human body; a cultural stage, lasting about seven days under tropical conditions, during which the larvæ absorb nourishment, grow, and develop; and a mature infective

stage, during which they are usually ensheathed and incapable of absorbing further nutriment from the faeces-soil admixture. Well grown infective larvæ can probably live up to six months under average tropical conditions; possibly much longer under specially favourable circumstances.

In the brief cultural stage the larvæ are especially vulnerable to physical agencies such as high acidity. These agencies, moreover, are also liable to impair the vitality of the developing ovum. On the other hand the mature larvæ are well known to be highly resistant to the action of a variety of disinfectants and other physical agencies generally harmful to living protoplasm.

The newly hatched larvæ are much more easily killed than either eggs or infective larvæ. (Cort 1921.)

In my paper under consideration I make only a passing allusion to the question of the effect of soil acid on hookworm larvæ. Dr. Chandler will find two additional references to the same subject in my Annual Report for 1923 in which I point out that the favourable influence of humus (Stoll 1923) as a nutriment for hookworm larvæ may more than counterbalance the effect of a low degree of associated acidity.

At the suggestion of the Colonial Advisory Committee I have undertaken to give the hookworm section of this report wider publicity elsewhere.

I am grateful to Dr. Chandler for drawing my attention to a possible misinterpretation of my meaning.

I shall be careful to point out explicitly that any agency directly affecting the viability of growing hookworm larvæ may indirectly influence the length of life of the adult infective larva.

It should, however, be clear from the context of the remarks quoted by Dr. Chandler and from the general tenor of my introduction, that I refer to the action of soil acid on the survival of hookworm larvæ under natural conditions.

The expression "hookworm larvæ" covers the whole history of the larva from its emergence from the ovum to its death or its penetration through the skin of man.

I mean exactly what I say.

The expression "mature infective larvæ" is frequently used in contradistinction throughout my papers.

If Dr. Chandler will turn again to the protocols of my experiments on the survival of hookworm larvæ amidst infected earth in baking pans, he will note that the ova-containing faeces were mixed with the soil under experiment, so that my figures for larval survival shown in Appendix III cover the period of egg hatching, and larval growth, in addition to the mature infective stage. In other words the conditions of these experiments represent what actually takes place in nature.

Soil acid is usually derived from either the humic group of acids or acid aluminium salts. If there be much decomposing vegetable matter

the oxidation of sulphuretted hydrogen may give rise to temporary traces of free sulphuric acid. Owing to the low ionisation of the acid aluminium salts it is probable that they would behave as a base in the presence of excess of humus, so that where both substances were present together their acid effect would not be exerted simultaneously.

Dr. Chandler does not give the chemical analysis of his experimental soils, but judging from the low nitrogen content shown by such analyses of Assam soils as I have seen, the acid under consideration is derived from aluminium salts. The highest acidity reached in Dr. Chandler's experiments was pH 5.2. Soils from the Straits Settlements may easily reach an acidity of pH 4.0. The figures 5 and 4 are logarithmic. They are minus powers of 10, i.e., the hydrogen concentration represented by pH 4 is ten times greater than that corresponding to pH 5.

It is necessary to bear in mind that a change in reaction may be merely indicative of other changes much more significant from the point of view of the life of hookworm larvæ, such as an anaerobic as opposed to an aerobic type of fermentation of organic matter.

It does not necessarily follow that it is the acid itself which exerts the devitalising action. It may be some other agency usually associated with distinct acidity.

Appendix I of my paper, containing the analyses of my soil by the Government Agricultural Chemist, gives the pH reaction of my experimental soils. Soils B and D had an initial acidity of pH 5.4 associated with 6.7 per cent. humus, 7.6 per cent. oxide of alumina and 1.34 per cent. lime in a combined form. The highest acidity reached in the Calcutta experiments was two degrees more acid than the Colombo soil. The larvæ in these two experiments with soils B and D lived as long as 124 and 120 days, respectively. The infective larvæ added to Dr. Chandler's moist acid soil lived 81 days on the same basis of calculation.

As a matter of fact the reaction of a soil-faecal mixture depends largely on the nature of the faeces. If they are derived from human beings fed on a vegetable diet, the products of decomposition are highly acid. (Stoll 1923.)

Stoll has suggested that the acid condition of human manure is a hookworm control asset. But human faeces may be alkaline.

The results of some of my experiments show a greater longevity of hookworm larvæ than has been obtained hitherto by any other worker in the tropics.

I attribute this unusual longevity to my good fortune in obtaining a supply of exceptionally well nourished larvæ. Optimum larval survival implies optimum conditions for larval production. In other words the longevity of hookworm larvæ depends primarily on good cultivation.

This is the main contention of my paper which includes the following sentence. "It follows,

therefore, that larvæ cultivated from human fæces by an unsuitable method would be delicate and unlikely to survive for any length of time."

To avoid further misunderstanding, I will endeavour to show how I was led to this conclusion. First it will be necessary to refer as briefly as possible to the laws of disinfection. Chick (1908) showed that the course of action of a given concentration of disinfectant on bacteria may be exhibited by a curve similar in form to that expressing the course of a unimolecular reaction in chemistry, so that if n^1 and n^2 = numbers of bacteria, and t_2 and t_1 = the respective times; the formula becomes

$$\frac{1}{t_2 - t_1} \log \frac{n^1}{n^2} = k,$$

k being a constant.

In practice this ideal formula has to be modified to meet the operation of varying age of the bacteria, the younger forms being the more resistant. Similarly a logarithmic relationship holds good for varying concentration of disinfectant and time taken to disinfect. Also reaction velocity increases with temperature in a manner similar to a chemical reaction. Similar laws appear to govern the action of other deleterious agents such as bacteriolysins.

In the case of hookworm larval development the matter is complicated from the start by the fact that the eggs as passed in the fæces differ between themselves in viability. Then the larvæ may be competing among themselves for the available nourishment. They may also differ in respect of the amount of oxygen available in various portions of the soil. And doubtless other factors capable of effecting larval vitality will enter into play. Other things being equal, however, the deleterious action of such a substance as an acid will in all probability exert itself in much the same manner as a disinfectant acting on bacteria. Some of the eggs will die, some of the developing larvæ will fail to reach maturity, while those that do mature will have their vitality affected in varying degrees. In such a case we may expect the influence of unfavourable cultural conditions to show itself in a low average longevity of the infective larvæ and a rapid falling off in larval numbers.

Suppose on the other hand the cultural conditions were ideal and every egg produced a healthy and well nourished infective larva enclosed in a sheath, then the average longevity of the larvæ would be very high and the curve of larval mortality would show a prolonged level culminating in an abrupt fall to the base line.

These considerations lead to an important point. The short average longevity of hookworm larvæ in the tropics as compared with temperate climes has been associated by myself and others with increased activity and consequent exhaustion of larval food reserve. But the effect of temperature in accelerating the action of any harmful agent during the period of development must also play a part.

It will be noted that I have not attempted to throw my figures representing the survival of hookworm larvæ into the form of a curve. This omission is deliberate; to have done so would have given a fictitious appearance of accuracy. The limited time at my disposal for this research did not permit of the adoption of a sufficiently exact technique for complete quantitative accuracy. But the facts warrant the conclusion that the rate of larval mortality was relatively low in the earlier weeks of the pan, and of one of the pot experiments. They, therefore, support the conclusion that I had hit upon good cultural conditions.

It must be remembered that the natural reaction of the soils used was modified, firstly, by acid generation from the fæces, and secondly, by alkali produced from the layer of wood-ash covering the pans.

Both Looss (1911) and Stoll (1923) have produced evidence to show that excess of acid in culture impairs larval production and larval viability. The initial effect is exerted on the eggs in the morula stage. The following paragraph is extracted from Stoll (1923), No. XVII, page 149. "Not only in the changing number of the larvæ secured by isolation, but by their striking differences in appearances, as derived from the charcoal and unmodified fæcal cultures, there were being emphasized the conditions of hookworm well-being in one case and its lack through environmental rigor in the other. To follow the day-to-day 'remarks' (Tables I and II), contrasting the charcoal and the fæcal cultures, gives a hint of this. Every additional day's observation of the forms from the bone-black showed typical stages in excellent condition. Those from the fæcal cultures, on the other hand, not only by their declining numbers, but by the lack of food granules and the presence of dead forms, evidenced the fact that the survivors were worms of a quality wholly different from the charcoal forms."

The unmodified fæcal cultures reached pH 4.8. No larvæ whatever developed in many of Stoll's straight fæcal cultures; in all these fæcal cultures the number of larvæ produced was insignificant compared with the number obtained from the corresponding charcoal cultures.

It is obvious that any impoverished larvæ reaching the infective stage in these acid cultures must have had low powers of continued survival.

In the Calcutta experiments the hookworm larvæ were not developed in the soil itself but separately in charcoal cultures; extracted on the seventh day, and then added to the surface of the soils under experiment.

Dr. Chandler says nothing about the reaction of the charcoal but presumably it was alkaline since Looss points out that acid charcoal is useless for developing hookworm larvæ.

We may reasonably infer, therefore, that mature infective larvæ in good condition were applied to the soil in these experiments.

Moreover, while developing larvæ live in the interstices of the soil, infective larvæ spend most of their time extended in the air upon the surface of the soil particles surrounded by a capillary film of soil liquor.

It is not surprising that so little difference was exhibited in the longevity of the added larvæ in soils whose reaction varied from pH 7.5 to pH 5.2.

The maximum larval longevity of 81 days obtained by Dr. Chandler is a little below what one might reasonably expect after making due allowance for the relatively high atmospheric temperature prevailing during the Calcutta experiments. Add seven days and compare the result, 88 days, with the longest life obtained in the Colombo pan experiments, 124 days. In the Colombo pot experiments infective larvæ were introduced into the surface layers of the soil. The maximum larval longevity was at least 120 days; adding 11 days for cultivation we obtain a total larval life of 131 days. But as I point out on page 24, larvæ must use up a certain amount of energy in the process of extraction. See page 4 of my preceding paper, "Looss is probably correct in considering the tendency of the mature infective larvæ to migrate into water to be an innate character of the organisms. It forms one of the tropic reactions which enable the parasites to reach their definitive host."

It follows that the results of neither my own nor Dr. Chandler's pot experiments really represent the true maximum of longevity of the hookworm larvæ under observation. The results are influenced by the intervention of an artificial procedure, namely, extraction of the infective larvæ from the cultures by Baermann's method.

We should be grateful to Dr. Chandler for providing us with valuable and interesting data regarding the longevity of infective hookworm larvæ on soil during the hot weather in Calcutta, but I fear that he has thrown little light on the general question of the survival of hookworm larvæ in acid soils under natural conditions.

His final conclusion that the acidity likely to be present in ordinary agricultural soils does not interfere with the survival of hookworm larvæ cannot be accepted as a legitimate inference from the results of his experiments, which are only applicable to the resistant stage of the life history of the larva.

SOIL ACIDITY AND SURVIVAL OF HOOKWORM LARVÆ.

A REPLY TO DR. HIRST'S CRITICAL COMMENTARY.

By ASA C. CHANDLER, Ph.D.,
Calcutta School of Tropical Medicine.

I REGRET that I misconstrued Dr. Hirst's meaning when he stated that acid soil is unfavourable to "the continued survival of hookworm larvæ." The fact that he speaks of its effect on development in the following sentence not unnaturally suggested that he made a distinction between survival and development, and that he was not thinking only of an *indirect* effect on survival due to an unfavourably influenced development. I am in full agreement with Dr. Hirst's ideas as amplified in his critical commentary of my paper.

I am sorry that Dr. Hirst misinterpreted my paper to the extent of inferring that I assumed that soil acidity exerts its main influence on the infective stage of the life history of hookworm larvæ and that my whole investigation was based on this erroneous assumption. I gladly agree with Dr. Hirst that such an assumption, had I made it, would have been quite unjustifiable and erroneous. I considered the development and the continued survival of hookworm larvæ as two separate phases of the problem, and purposely confined myself to a consideration of the latter phase, having planned to investigate the former by an entirely separate set of experiments. In order to eliminate the influence of acidity on development and the consequent indirect effect on survival it was *necessary* to use healthy, vigorous larvæ hatched and developed under identical conditions, if the influence of soil acidity on the longevity of infective larvæ was to be studied, and I tried to make it clear in my opening sentence that this was the object of my experiments; it did not occur to me that omission of a discussion of effect on development would be construed as suggesting that there was no such effect. I am grateful to Dr. Hirst for giving me an opportunity to correct such a misunderstanding.

Dr. Hirst suggests that the effect of soil acidity could be studied by merely mixing fæces with soils of different acidity and composition and observing the effect on development and survival of the larvæ. To my mind the problem is not so simple, otherwise the experiments on this phase of the question would have been done long ago. When one mixes fæces with soil a great variety of new factors are introduced, as Dr. Hirst himself hints. The acidity of the fæces, the decom-

position products as they decay, their nutritional value, the reaction of their constituents with the constituents of the soil, the relative proportions of soil and faeces and the nature of the soil-faeces mixture are all factors of the utmost importance, and may very well overbalance any effect which a moderate degree of soil acidity, such as is ordinarily found in agricultural soils, might have. One's object in such an investigation is, of course, to find out what happens ordinarily in nature, and one must simulate natural conditions as closely as possible. In Bengal and Assam the natural course of events, after a stool is deposited on soil, is for the faeces to be very thoroughly intermixed by dung beetles with the underlying soil, which is dug up into a loose granular pile. The proportion of soil to faeces when the process is completed, say in 24 hours, probably does not vary within very wide limits, but even if one ascertains approximately how many grams of soil is mixed with a gram of faeces it is impossible in the laboratory to simulate the beetle mounds in a satisfactory manner by artificially mixing faeces and soil. I have tried it repeatedly without success. Consequently to satisfactorily study the influence of reaction of soil in nature one must place samples of single stools (in order to avoid differences in acidity, composition, etc.) on the different soils to be tested and expose them where they will be naturally mixed by dung beetles, and the experiment should be repeated with faeces of different types. Moreover, as Dr. Hirst has intimated, it is impossible to study soil acidity alone, without consideration of other characteristics of the soil, e.g., humus content, mineral constituents, available food material, etc. For these reasons the study of the effect of soil acidity on the development of hookworm larvæ is a very difficult and complicated thing. The effect on the developed larvæ is a comparatively simple thing, for in nature the influence of the faeces has usually largely disappeared by the time the larvæ have matured, and the soil alone need be considered. It seemed worth while to find out as a preliminary whether the larvæ, once developed, would be influenced by mild acidity, and my experiments showed that such was not the case. That healthy infective larvæ do develop in considerable numbers in acid soils is certain, since I have isolated over 1,200 from half a pint of Assam soil having a pH of 5.5, all of them, so far as could be judged by appearance, very healthy and well supplied with nutritional granules. It is, therefore, interesting to know that such larvæ have just as good chances of survival as if they were on neutral or slightly alkaline soil.

A NOTE ON SOME PREDISPOSING FACTORS IN ASTHMA.

By M. A. KRISHNA IYER, I.M.B.,
Alipuram Jail, Bellary.

Few medical men have successfully treated and cured a real case of asthma. The truth of

this remark is borne out by the very many and very varied lines of treatment in vogue. Injections of peptone solution have stopped the attacks in some cases for two years, whilst in others soamin injections have been successful. Spraying of the mucous membrane of the nasopharynx has succeeded in some cases, whilst regulation of the diet has benefited others. Inhalation of the fumes of nitre paper has given considerable relief to some patients, whilst patent stramonium cigarettes have relieved others. Administration of calcium salts is resorted to by some doctors, whilst others claim that giving potassium iodide greatly lengthens the intervals between attacks. We have to-day no rational, standardised and single mode of treatment for asthma.

Yet an investigation of the causative factors is not unimportant, as the following cases may shew:—

Case 1.—A rich Brahmin landlord whom I was called in to attend in his village. After giving the usual type of injections, and administering a mixture of potassium iodide, belladonna, and lobelia, etc., he recovered within a few days. A few months later he got another attack, whereupon a similar line of treatment did good. On close enquiries, however, I found that his attacks always occurred during the padi harvesting season. It is customary in South India for the padi to be heaped up in different places inside the dwelling houses before it is all finally collected from the fields and then stored in the granary. The patient's attacks always came on during this process, when he had to move about inside the house amidst stored heaps of fresh padi.

Case 2.—A male patient aged about 50 who is an oil monger, and prepares gingelly oil by expression of the oil from seeds in an oil press worked by bullocks. He gets the attacks of asthma regularly during certain seasons of the year when there is a special demand for this oil in connection with certain festivals, and when he is especially busy at this type of work almost exclusively.

Case 3.—A woman who gets her attacks regularly during the "flowering season." Her occupation is to make garlands for the deity in the temple. At certain seasons of the year there are different flowers in season which are used to make the garlands, and it is at such seasons that her attacks of asthma come on.

Case 4.—A woman who cannot tolerate certain articles of diet; for instance buttermilk never agrees with her and invariably precipitates an attack.

From such cases one sees how climatic seasons, food, different occupations or commodities which one is obliged to handle may be the undoubted causes of and the immediate stimulating factors in attacks of asthma. Similar cases have been reported in other medical journals, such as the occurrence of attacks of asthma after using a pillow stuffed with a certain species of down and of their cessation when the pillow was changed. Further, in the issue for March 1925 of the *Indian Medical Gazette*, Majors H. W. Acton and R. N. Chopra, I.M.S., have recorded similar instances. In such instances a careful enquiry into all the circumstances associated with the attacks and the taking of appropriate measures for the avoidance of the stimulus which provoked the attacks may effect a cure.

A Mirror of Hospital Practice.

A CASE OF SNAKE-BITE TREATED WITH ANTIVENOMOUS SERUM.

By L. A. P. ANDERSON, M.A., M.D.,

MAJOR, I.M.S.,

(From the Central Research Institute, Kasauli.)

REPORTS of cases of snake-bite which have been treated with antivenene, and which have recovered, are not uncommon in the medical press, but it is, perhaps, less common to have an opportunity of reporting a case (a) in which the victim had certainly been bitten, (b) in which the biting snake was undoubtedly of a well-known poisonous variety, (c) in which treatment was begun so soon after the bite that the chances of saving life were favourable, even if a lethal dose of venom had been injected, and (d) in which systemic injection of antivenene alone was relied on for treatment.

The patient, a robust Hazara cooly, aged about 35 years, was bitten by a daboia (*Vipera russellii*) on the first phalanx of the left forefinger.

He came straight up to the Central Research Institute—a distance of about $\frac{3}{4}$ of a mile up a steep climb—reaching there about half an hour after receiving the bite. He brought the snake

with him—alive and uninjured—holding it by the back of the neck and the tail. The snake was a moderate sized Russell's viper, $2\frac{1}{2}$ feet long and 4 inches in girth.

When first seen, the man was pale and shocked, sweating profusely and with a full bounding pulse. He had two well-marked fang punctures on the back of the left forefinger. One of the punctures had been converted into a linear cut, the result of dragging off the snake. The finger was considerably swollen, and the wounds were sealed with clotted blood. There was no doubt whatever that the fangs had really penetrated.

He had applied no ligature, but had followed the common Indian practice of tying a piece of rag somewhat firmly round the part above the wound, in this case the left wrist.

He stated that on the way up to the Institute he had vomited twice, and that the vomit contained blood.

As soon as the patient arrived, about half an hour after receiving the bite, he was given 80 c.c. of Kasauli antivenene intravenously into the median basilic vein. The actual wounds were dressed with iodine and bandaged, but no other local treatment was given.

Almost immediately after the injection of antivenene the patient vomited and continued to do so at frequent intervals for about an hour. Diarrhoea then set in and he passed four or five large liquid stools in about fifteen minutes; neither the stools nor the vomit contained blood.

Forty minutes after treatment was begun, and about 70 minutes after receiving the bite, there was marked oedema of the left hand and wrist, and the man complained of severe pain in the hand and arm up to the axilla. He also complained of chilliness, thirst and drowsiness. Eighty-five minutes after the first injection, he was given a second intravenous injection of 80 c.c. of antivenene.

Beyond these two injections of antivenene he received no other treatment except that he was kept warm and given such drinks as hot tea and milk, or water, when he complained of thirst. He remained quite quiet, lying on a "charpoy" in front of a stove, and except for drowsiness, thirst and local pain he exhibited none of the symptoms of daboia poisoning. Throughout the time he remained at the Institute—about five hours—his pulse and respiration remained good; the former never rose above 100 and the latter varied between 19 and 26 per minute.

As soon as it seemed certain that the man's life was no longer in danger, he was transferred to the Cantonment General Hospital for observation and any further treatment which might be necessary.

On admission there, the site of the wound was incised and permanganate crystals were rubbed in. This was about six hours after the bite.

The man remained in hospital for four days. He showed no ill-effects from the bite except

pain in the arm which was very troublesome for 24 hours, and marked cedema of the hand and forearm on the affected side. There was still some cedema of the dorsum of the hand when he was discharged from hospital.

Two days after his discharge a pre-existing boil on the back of the left wrist developed into an abscess, which was incised and treated in the usual way. The boil had no connection with the snake-bite.

On the 8th day after the serum injection he developed a serum rash, chiefly marked over the buttocks and back. He was re-admitted to hospital and detained 3 days, by which time the rash had disappeared.

COMMENTS.

While it is, of course, not possible to be sure that the patient had received a lethal dose of venom, yet the snake causing the bite was of sufficient size to have injected a fatal dose and the condition of the wounds showed clearly that penetration of the fangs was complete and that the snake had got a good grip. The man had walked up a considerable hill, about 500 feet, to reach the Institute, and the resulting acceleration of the circulation, with no tourniquet on the part bitten, must have given the venom every chance of reaching the systemic blood-stream even taking into consideration the well-known variability in the rate of absorption of daboia venom.

No local treatment was given until 6 hours after the bite, and reliance was placed on the rapid administration of the specific antivenene.

The local condition, cedema, etc., showed that a certain amount of venom, at any rate, had been injected.

No general symptoms of daboia poisoning supervened, except drowsiness and thirst. It is probable that the vomiting immediately after the bite was due to shock and fright, and the later emesis and the diarrhoea were probably the result of the serum injection.

Recovery was complete, and except for a small sloughing ulcer at the site of the bite, and slight cedema of the left hand, no signs of his accident remained when the man presented himself to be photographed four days later.

I am indebted to Sub-Assistant Surgeon Sangat Ram, in sub-charge of the Cantonment Hospital, Kasauli, for the man's after history, and to Lieut.-Colonel S. R. Christophers, C.I.E., O.B.E., I.M.S., Director, Central Research Institute, Kasauli, for permission to publish this case.

A CASE OF KALA-AZAR IN THE SIMLA HILLS.

By B. J. BOUCHE, I.M.D.,

Assistant Surgeon, Jutogh, Simla Hills.

THE following case of kala-azar may be of interest to some of the readers in Northern India as exemplifying a much-too-common obsession of

"chronic malaria" in all fevers which baffle a better diagnosis.

The patient, an Anglo-Indian, girl, 12 years of age, arrived at Jutogh, Simla Hills, from Sanawar, on 1st June, 1925, for the Whitsuntide holidays with a statement from a medical officer, that she was suffering from "anaemia" the result of "chronic malaria," recommending that she be kept at Jutogh with her mother for a month.

Condition on Admission.—Marked anaemia, ill-nourished and emaciated, spleen enlarged 3" towards umbilicus, and temperature 99.4°F. Tongue fairly clean; liver slightly enlarged downwards; haemoglobin 75 per cent.; weight 79½ lbs. Blood negative to malaria.

Previous History.—Fever some 8 years ago, when living in Madras, which was negative to enteric and suspected to be kala-azar. The patient has had fever of low irregular type and was repeatedly treated for malaria with no benefit. She was in hospital at the Sanawar School frequently and about a year ago was in association with a case of kala-azar there. The patient's aunt also suffered with kala-azar and the patient was in contact with her before coming in touch with the case at Sanawar.

6th June, 1925.—No response to quinine (grs. 5 t.d.s.) given from 2nd June, 1925, 9-30 p.m. Temperature 106°F. Intravenous injection of quinine bihydrochloride (grs. 3).

7th June, 1925.—8 A.M. Temperature 98.6°F. Intravenous injection of quinine bihydrochloride (grs. 2½). Urine now distinctly "milky," showed marked chyluria and the microscope revealed a large number of microfilariae. The quinine was now increased to grs. 10 t.d.s. and a mixture of tinct. ferri perchlor. and glycerin was added as an anti-filarial measure.

9th June, 1925.—Slight epistaxis.

10th June, 1925.—Intramuscular quinine bihydrochloride (grs. 3); great difficulty was experienced in entering the veins.

The patient was placed on the "seriously ill" list although clinically her condition was remarkably good with a minimum of disturbance. The appetite was retained throughout the fever and the patient demanded her curry and rice.

The finger blood was examined for the fifth time for malaria without success. Leishman-Donovan bodies were seen in three large mononuclear leucocytes.

11th June, 1925.—Chyluria disappeared but filariae still persisted in the urine. Quinine omitted for one day on account of indigestion.

13th June, 1925.—Napier's formalin test positive.

16th June, 1925.—Urea stibamine intravenously (0.035 grm.)

Quinine was now permanently omitted.

A severe urticarial eruption broke out immediately after the urea stibamine injection, accompanied with nausea and vomiting, but in half an hour's time the patient was quite calm and well. Large doses of sodium bicarb. (1 drachm) were

frequently given by the mouth in milk and water.

18th June, 1925.—Second intravenous injection of urea stibamine (0.075 grm.). This was given in one of the large pre-malleolar (internal) veins of the right foot as the conventional veins in the elbows were both still suffering from the previous trauma.

20th June, 1925.—The foot was acutely inflamed and blistered in parts, for which suitable treatment was applied.

From 22nd June, 1925 to 21st August, 1925, the patient was given doses of 0.45 grm., 0.1 grm. and five doses of 0.2 grm. each—a total of 1.66 grms.

The temperature which had been running up to 104°F. came down to normal after the third injection of urea stibamine and did not rise subsequently.

The weight of the patient is now 85½ lbs., representing an increase of 6 lbs. since she first came under treatment—a period of ten weeks.

1st September, 1925.—The patient has now completed the treatment and is in all respects "fit."

I am indebted to Major A. Gardner-Brown, R.A.M.C., Officer Commanding, British Station Hospital, Jutogh, for his kind permission to publish these notes.

A FOREIGN BODY IN THE PELVIS.

By K. M. NAYAK,

Assistant to District Medical Officer, Vellore.

A FEMALE patient Chellamma by name was admitted on 16th August, 1924, into the Government Pentland Hospital, Vellore, for a swelling on the right side, immediately above and behind the highest point of the crest of the ilium. The swelling was well marked, oval in shape, and about the size of a duck's egg. It was slightly painful, a little tense and fluctuating. Her temperature was 99°F and pulse 74; general condition good. She was fairly well nourished, of good physique and appeared to be in the enjoyment of sound health. No information could be got from her regarding the previous history. So the diagnosis lay provisionally between a suppurating hæmatoma and a tubercular abscess of the spine pointing in the iliac region. She was prepared for operation and under chloroform anaesthesia the swelling was incised. Nearly 2 ounces of curdy matter tinged with blood was evacuated, the cavity was irrigated and just before closing the cavity was explored with the finger. It was occupying the upper part of the right iliac fossa. The cavity was retro-peritoneal and the floor of the cavity was formed by the iliac bone and at the bottom of it a small hard pointed object like a spicule of bone was striking against the tip of the finger, at the same time conveying to the finger the same sensation as is felt when a tuning fork is struck. The projecting end of the same object was caught with a pair of artery forceps and on gently

pulling, out came a piece of coconut broomstick 4 inches long. These broomsticks are generally used here in the Madras Presidency for preparing swabs for painting with tincture iodine. This piece of broomstick was covered with a thin layer of white incrustation along its whole length, thereby giving us an idea that it must have been lying in the tissues in the iliac fossa for some time. Though a tentative diagnosis had been made beforehand of a suppurating hæmatoma, there was absolutely no history of any injury from outside and there was absolutely no evidence to suspect that the broomstick found its way from outside by piercing the skin and lodging itself in the right iliac fossa. Hence, while the patient was still under chloroform, we immediately put her in the lithotomy position, opened out her vagina by a duck bill speculum and, on examining the interior, found out on the right wall of the vagina, a small red ulcerated opening with a small bead of whitish pus at its orifice and which admitted the end of a metal probe, and our suspicion that the broomstick must have been introduced per vaginam was confirmed.

A drainage tube having been inserted into the abscess cavity, the wound was dressed and the patient was taken to the ward. She had an uneventful recovery and was discharged on the eighth day. On coming round from the effects of chloroform the patient, when she was minutely questioned, gave the following interesting story with the greatest reluctance and after the greatest persuasion, that she was aged 16 years and married for the last 2 years. Six months ago her husband had left her destitute and homeless. He having gone to Penang as an emigrant in a labour corps had left her to her wits and to the tender mercies of his relations. Having been thrown astray in this wicked world, homeless and penniless, and surrounded by temptations she had naturally gone astray, and she became pregnant. Being unable to hide her condition any longer, the guilty woman sought the help of the village barber, midwife or *dhai* at the end of the fourth month, and this worthy woman introduced this piece of broomstick to cause abortion. Instead of pushing it into the uterus she pushed it the wrong way outside the cervix, pierced the vaginal wall and sent it right home into the right side of the pelvic wall. I am pretty certain she had used considerable force before she achieved her object. Abortion resulted within 24 hours. The foetus came out, but not the instrument that was used to produce the abortion, which remained embedded in the tissues of the pelvic wall. Beyond causing slight dull aching pain and discomfort while walking, the patient was not in any way inconvenienced by the presence of the broomstick inside her pelvis, till at the end of 2 months (2 months after the abortion) she noticed a slight painful swelling on the right side, immediately above and behind the highest point of the crest of the ilium. This swelling gradually increased in size

and in the course of 10 days attained the size of a duck's egg and made her seek admission into the hospital. It is quite evident that muscular action was responsible for bringing it to the surface, and that the pilgrimage and the journey to its destination had taken 2 months to be accomplished. The *dhai* was responsible for the entry and Nature was responsible for the exit. It is also remarkable to note the friendly attitude of the structures of the pelvic wall, especially those at the brim in giving a free unchallenged passage to the foreigner. It stands to reason that the broomstick passed beneath and behind the big iliac vessels while crossing the brim of the pelvis and at the same time not injuring them. I have no doubt that the broomstick was retro-peritoneal.

A CASE OF HIRUDINIASIS OF THE MALE URETHRA.

By Capt. P. N. MITRA, M.B., D.T.M. (Cal.),
Civil Assistant Surgeon, Assam.

A PATIENT, M. M., aged 8 years, came to hospital at 4 P.M. in October 1925 with the following history.—He was fishing with a rod at about 12 noon in a marsh (*bhil*), standing knee-deep in water without any clothes on, when he suddenly noticed a leech entering his external meatus urinarius. He tried to pull it out but the leech slipped inside and he had been unable to pass any urine and blood dripped from his urethra.

On examination I found blood dripping from the external meatus and his clothing over the corresponding area was soaked with blood. A soft rubber catheter was passed and met with no obstruction; bright red blood diluted with urine was drawn out of the bladder. The bladder was washed out and the washings returned blood-tinged. Some strong salt solution and adrenalin was left in the bladder, the catheter withdrawn and the patient put to bed. No voluntary micturition was possible the next morning. Bloody urine was again withdrawn through the catheter, strong saline and adrenalin being repeated as before. As voluntary micturition was not possible catheterization was repeated in the afternoon and again next morning. During the last a certain amount of dark-brown granular blood was withdrawn. Catheterization was repeated in the afternoon with the same result, and during the night the leech was passed out with violent colicky pains. It measured 4 in. by $\frac{1}{2}$ in.; the mouth and anus were open and dark granular blood could be pressed out of its abdomen.

The points to be noted are:—

- (1) The rarity of the accident.
- (2) The leech bit at one or more points in the anterior urethra and then passed into the bladder where it fed itself.
- (3) It was killed by salt solution.
- (4) After death of the leech the sphincters relaxed, permitting regurgitation of some of its abdominal contents.

- (5) It then became flaccid and engorgement occurred leading to its spontaneous extrusion.
- (6) The boy was circumcised.

AN OUTBREAK OF ANTHRAX CONTRACTED FROM HANDLING INFECTED BEEF.

By A. K. MUKERJI, D.P.H.,
District Health Officer, Tipperah.

AKRAM ALI, a villager of Sripur, Tipperah, slaughtered a cow in order to give a feast. Within three to seven days of the feast Akram Ali, Imam Bux, Rahim Bux, and Medur Ali, who had all taken part in killing the cow and dressing the meat, developed malignant pustules. They were attacked with malignant pustules on the face, forehead or hands, attended with high fever. Imam Bux was the first to be attacked, on the 27th August, 1925, and died on the 30th. His son Rahim Bux, and Akram Ali both died on the 1st September, and Medur Ali two days later.

As a result of this outbreak a state of terror prevailed among the villagers, and I proceeded to Sripur to investigate matters. I found four further cases who were still suffering from malignant pustules, the pustules having broken down and forming the characteristic ulcers, as shown in the illustration on p. 23. The ulcer on the back of the adult female patient had given rise to much sloughing and had exposed the tendons. Films and scrapings from the ulcers showed anthrax bacilli, together with numerous staphylococci and streptococci. On enquiry it was reported to me that all three persons had handled the infected meat before cooking it. Further, the villagers reported that two cows belonging to one of the infected families had died two months previously quite suddenly, having been ill for only six hours, with a sanious discharge from the nostrils, mouth and intestine. The villagers also stated that the cow which had been slaughtered for the feast was diseased. The villagers in Sripur have no trade in hides, but are cultivators, and I was unable to trace any other possible source of infection except those mentioned.

The ulcers were treated with antiseptic dressings and eusol lotion, and precautions taken to prevent the spread of the infection to others. A point which I noticed was that, although these infected persons were freely in contact with others and no precautions had been taken to prevent the spread of the disease before my arrival, there were no further cases. Possibly the anthrax bacilli had become attenuated on passage through man, a less susceptible host than the cow.

Outbreaks such as this often fail to come to the notice of the public health authorities, whilst the villagers are quite ignorant of the risks run by both human beings and cattle from the slaughter of infected animals.

A CASE OF BILATERAL DISLOCATION OF THE LENS.

By Dr. ARTHUR H. DRIVER, M.B., Ch.B. (N.Z.),
*Medical Superintendent, London Mission Hospital,
 Jammalamadugu, Madras Presidency.*

THAIGADU, a village coolie, who came for treatment on account of impaired vision, presented a curious condition on examination.

The lens of the left eye was completely dislocated, moving freely in the anterior chamber with the movement of the eyeball. It showed only a very slight central opacity. The iris was tremulous and its free rim atrophic and coloured a light blue, contrasting with the deep brown of the body of the iris. Vision 2/36.

No lens could be seen in the right eye on first examination. The iris of this eye was tremulous and discoloured as in the other eye, but on getting the patient to lean forward a white cataractous mass floated up from the depths of the vitreous, appearing to fill the anterior chamber. Vision, perception of light only: tension, slightly plus.

Both eyes were operated upon on the same morning. The lens of the right eye was transfixed with a Bowman's needle with the patient sitting, the only position in which the floating lens could be caught. It was then rotated slightly inwards to make room for a clear incision, which was most conveniently done in the lower quadrant. The transfixed lens was then easily manoeuvred on to a spatula and extracted in the capsule. No vitreous loss.

Removal of the left lens was straightforward, the lens escaping immediately after incision.

Reaction was slight only in both eyes; perception of light was retained in the right eye, whilst the vision in the left improved to 3/12 with a + 14 lens.

Only a vague history of pain and redness in the right eye two years before admission could be obtained, with similar symptoms in the left eye for one year before admission. The patient persistently denied having had couching or any other form of treatment. It is difficult to believe that the right lens of this case was not couched and yet is it not possible, though of course rare, for a cataractous lens to become free of its ligaments without interference? Further, the condition of the anteriorly dislocated, non-opaque lens of the left eye certainly did not suggest couching.

The following pathological notes on the lenses were supplied to me through the courtesy of Major R. E. Wright, B.A., M.D., I.M.S., Superintendent, Government Ophthalmic Hospital, Madras:—

"Both the lenses are markedly smaller than normal. The clear lens is 6.5 mm. in diameter, almost globular. The opaque lens is of approximately the same diameter as the clear one, but more flattened antero-posteriorly. It is very hard and densely opaque throughout, the nuclear portion being more opaque and friable than the cortex. The capsule shews irregular thickenings and strips readily from the lens."

EXPULSIVE HÆMORRHAGE IN CATARACT OPERATIONS IN RURAL PRACTICE.

By K. B. ISRAIN, L.C.P. & S., L.M.P.,
Daharki, Sind.

ONE of the chief complications in the intra-capsular operation for cataract in rural practice in India is expulsive hæmorrhage. Village patients allow one no opportunity to prepare them for operation beforehand, and the result is sometimes expulsive hæmorrhage,—partly due to a glaucomatous tendency, partly to a nervous tendency on the part of the patient. The following two cases may be cited:—

Case 1.—An adult female patient operated upon on the 24th March, 1925. After cocainising three times with a 10 per cent. solution, I began the operation. As soon as the corneal incision in the right eye was finished the lens came out, accompanied by vitreous and followed by profuse bleeding. I at once instilled 1 in 1000 solution of adrenalin chloride and made my assistant press on the eye with a cotton-wool swab soaked in perchloride lotion. In the meantime I carried out the operation on the left eye with satisfactory results.

I then changed the swab on the right eye and bandaged the patient, but the bleeding did not stop. The patient was put to bed and $\frac{1}{2}$ grain of morphia given hypodermically, and a dose of calcium chloride by the mouth. The latter dose she immediately vomited. Half an hour later the dose of calcium chloride was repeated, but was again vomited.

That night the patient had no sleep, whilst the bleeding continued. I next administered 20 m. of adrenalin chloride solution hypodermically and gave calcium lactate, grs. 15 in solution orally, the dose being repeated every half hour. The bleeding now stopped. Next day the dressings were changed. On the eighth day the left eye was found to be doing well, but the right eye was shewing a tendency to protrusion. This eye was treated with instillations of silver nitrate, grs. 10 to the ounce, and the patient was discharged at a later date.

Case 2.—A male patient, aged about 60 years, presented himself for double cataract operation. The operation was carried out successfully by the usual intra-capsular method and the patient carried to his cot. Half an hour later he complained of a reeling sensation in his head and of burning pain in the right eye. The bandage was found to be soaked with blood. A subcutaneous injection of 20 minims of adrenalin chloride solution was at once given and the patient given eight doses, at half hourly intervals, of calcium lactate mixture. Next day the dressings were changed, when there was found to be bleeding from the left eye. On the fifth day the left eye was again examined, after having been left alone during the interval, and was found to be doing well. On the fifteenth day the patient was discharged.

Points of interest about the two cases are:—

(1) The hypodermic injection of adrenalin chloride solution appeared to be more efficacious than injections of morphia in controlling the hæmorrhage.

(2) Calcium lactate appeared to be better tolerated in aqueous solution orally than was calcium chloride when the patient was predisposed to vomiting.

(3) The left eye in both cases was normal or almost normal despite the hæmorrhage in the right eye.

(4) The failure of half a grain of morphia

in the first patient's case to secure sleep or even restfulness.

A CASE OF SEVERE ABDOMINAL INJURY.

By ROMENDRA K. BASU,
Assistant Surgeon, Damka, Balasore.

THE publication on p. 269 of the issue of the *Indian Medical Gazette* for last June of Dr. Row's case of abdominal injury prompts me to record one of still more serious abdominal injury.

The patient, J. M., a Hindu male, aged about 24, was brought to the Balasore Hospital about 8 A.M. on 28th October, 1924, with a history that he had been gored by a buffalo the previous evening. Some 5 feet of intestine had protruded through the rent in the abdominal wall and had been at once wrapped up in the filthiest of rags. In this condition he had been carried to hospital a distance of some 12 hours' transit in a *dooly*.

On admission his condition was very bad, and before operation $1\frac{1}{2}$ pints of normal saline with pituitrin was injected subcutaneously into the right axilla. On examination under chloroform anæsthesia it was found that the eviscerated gut was perforated in 3 places, each rupture being about 1 inch by $\frac{1}{2}$ inch in size, and the three perforations being close together. The exuded serum bathing the torn gut was mixed with solid faecal matter.

The torn gut was cleansed with hot saline, but no general irrigation of the peritoneal cavity was resorted to. On attempting to suture the torn gut with Lembert sutures the ragged margins of the rents gave way; finally the tears were repaired by using both Lembert and purse-string sutures. In order to replace the intestine within the abdominal cavity the original wound had to be enlarged. The sites of the tears in the gut were touched with pure "Electrolytic chlorine" before replacement, the wound three-quarters closed, and drainage resorted to.

Two injections, each of gr. 1/100th of atropine, and an injection of pituitrin and one of hyoscine were given the same day. The patient's condition was critical for two days. The day after operation the wound was opened up. It was found to be whitish in colour from the action of the "E. C.", and some stitches which had torn out were removed. The wound itself was now treated with pure "E. C." and "E. C." dressings were applied daily; 48 hours after operation the patient passed a stool and a rectal tube was inserted to relieve flatus.

On the third day after operation general peritonitis seemed threatening, with persistent hic-cough. Atropine and strychnine were given hypodermically and nothing by the mouth except sips of warm water. After two weeks of dressing with "E. C." lotion the patient was out of danger, and was discharged cured, although it was a month after operation before he could

walk unaided. Dr. S. C. Mitter, the Civil Surgeon, took considerable personal interest in the case.

The patient's recovery after so severe an injury is remarkable, whilst the use of electrolytic chlorine appears to have been of undoubted benefit.

A CASE OF STRANGULATED HERNIA.

By HUKAM CHAND GUPTA, B.Sc., M.B., B.S.,
Assistant Surgeon, Civil Hospital, Mardan,
N. W. F. Provinces.

MIRO, Mahomedan male, aged 28, was admitted to this hospital on the 19th February, 1925, with the following symptoms:—Hiccough of 24 hours' duration; vomiting of fluids—yellowish green in colour, but not of faecal odour; great restlessness; and acute pain in the right inguinal and scrotal region.

Examination shewed a hernia about 4 inches long by $2\frac{1}{2}$ in. diameter. He had been the subject of congenital hernia since birth, and for the previous six days the swelling, previously easily reducible, had been irreducible. He had a pinched look with sunken eyes and clammy skin; temperature 99° , pulse 110, of low tension and with an occasional missed beat; abdomen tympanitic all over but fairly soft; complete constipation for six days; constant retching and vomiting of all fluids taken by the mouth. The scrotal swelling was hard, tense, painful on pressure, dull on percussion. The skin over it was discoloured and reddish brown in colour.

Immediate operation was resorted to under chloroform-ether anaesthesia. On opening the hernial sac fragile material resembling blood clot was discovered. On irrigating this with hot saline it was discovered to be a piece of the great omentum which had undergone dry gangrene. On relieving the constriction at the internal abdominal ring a piece of small intestine, about an inch in length and of normal colour, was found in the sac.

The gangrenous portion of the great omentum was transfixed, ligated and removed. The portion of small intestine was returned to the abdomen; the operation completed by closure of the hernial aperture; and the parts stitched up, as there was no marked effusion during the operation. The patient made an uneventful recovery.

Points of interest in the case are:—(1) The rapid recovery after operation, despite the critical state of the patient on admission, owing to the fact that the intestine was not affected. (2) Hiccough stopped the same evening, after half a c.c. of pituitrin had been given hypodermically an hour after the operation. (3) A tentative movement of the bowels the morning after operation, followed by a full evacuation the next morning after a dose of castor oil. (4) The absence of distension of the abdomen following upon non-affection of the gut, the strangulation being confined to the great omentum.

THE VAGARIES OF MALARIA. THE HEPATIC TYPE.

A Note by—Dr. A. BAYLEY-DE CASTRO,
Junior Medical Officer, Haddo, Port Blair.

FROM time to time one has read articles in the *Indian Medical Gazette* on rare manifestations of malaria, and in text-books one reads of algid and pernicious forms, but I do not think that the "true hepatic form" of the disease has been recorded, and therefore I take the liberty of publishing this note. Last year I had three such cases in my hospital, and this year so far one has been admitted.

Patient No. 45971, a Moplah, reported sick on the 9th May, 1925, complaining of fever and diarrhoea. Both the liver and spleen were slightly palpable and tender. The tongue was clean and the pulse strong in force and normal in frequency. The temperature was normal, and blood films at this date failed to shew malarial parasites, but shewed distorted red corpuscles. The stools failed to shew *Entamoeba histolytica* or ankylostome infection, but contained a little slime.

The next evening he complained of very acute pain in the right hypochondrium and on the morning of the 11th there was rigidity of the upper abdominal muscles and marked tenderness over the liver, together with slight distension of the abdomen as observed in the flanks. The board-like hardness of the abdominal wall prevented palpation, but light percussion shewed an increased dullness upwards to the right nipple and downwards to four finger-breadths below the costal margin. The temperature was normal, the pulse strong and 74 per minute. Blood films now shewed abundant malignant tertian malarial crescents and the total leucocyte count was 13,000 per c.mm.

Owing to this high figure half grain injections of emetine daily were resorted to and intravenous injections of 10 grains of quinine bi-hydrochloride daily, together with a mixture containing quinine and arsenic by the mouth. On the 13th, the enlargement of both the spleen and liver was considerably reduced.

14th May. Total leucocyte count 9,280 per c.mm. Tongue coated with white fur. A localised and very tender spot below the right costal margin. Liver dullness reduced by some half an inch both below and above. Some tendency to constipation, for which a calomel purge was given.

16th May. Liver dullness reduced to the level of the 8th rib above and of the costal margin below. Slight icteric tinge in the conjunctivae and a trace of bile in the urine. Blood films still shewed malarial crescents present. In spite of the severity of the hepatic condition, the patient had not suffered much constitutionally.

The enlarged and acutely congested liver remained as such until the 16th, and there was a certain amount of general constitutional disturbance and pyrexia to 101°F . The patient, however, did not look seriously ill; a liver affected to the same extent by any other infection would undoubtedly have brought about a grave, prolonged and striking constitutional disturbance.

20th May. Crescents still present in blood films. Temperature normal, tongue clean, appetite good, bowels regular, general condition excellent.

25th May. Crescents not found in films. Liver normal. Spleen enlarged to half an inch below the costal margin, hard to the touch.

31st May. Discharged to the post-malarial gang for one month. Feels and looks fit.

In all, the patient had three intravenous injections, each of 10 grains of quinine, and six injections, each of half a grain of emetine. He was on the quinine and arsenic mixture orally up to the date of discharge from hospital.

Points of interest in the case are:—

(1) The acute and rapid enlargement of the liver.

(2) The predominance of hepatic symptoms.

(3) The rigidity of the upper abdominal segment, and especially of the right rectus muscle.

(4) The high total leucocyte count.

A differential leucocyte count, carried out on the 14th May, gave the following figures:—eosinophiles 2 per cent.; polymorphonuclears 65 per cent.; lymphocytes 18 per cent.; large mononuclears 18 per cent.

(5) The absence of marked constitutional disturbance in proportion to the severity of the symptoms; the patient's weight on admission was 109 lbs.; on discharge 107 lbs.

In conclusion, I may mention another case of malignant tertian malaria; patient No. 45690, a man of burly physique, 34 years of age. He was in hospital from the 19th July, 1924, to the 13th August, 1924, with a normal temperature throughout. Blood films shewed numerous malarial crescents; but his only complaint, during the first four days of illness, was of excruciating pains in the head which had driven him to hospital. Big man though he was, he used to cry like a child. He had no other symptom.

THE GASTRO-INTESTINAL TYPE OF MALARIA.

By MADAN H. JHAVERI, M.B., B.S. (Bom.),

*Medical Officer, Loimwe, Kengtung Sub-division,
Southern Shan States, Burma.*

DURING the first six months of 1925, I had five cases of malaria with marked gastro-intestinal symptoms. The patients were all admitted complaining of severe abdominal pain, vomiting, constipation, a very tender abdomen, a pulse full and bounding, with a high temperature, and later collapse. In short the symptoms suggested more or less typical acute peritonitis. In two of the cases there was diarrhoea.

All five patients were military police sepoy with a previous history of malaria. On admission an injection of 10 grains of quinine was given intramuscularly, and within two hours the symptoms were relieved. Next day a further injection of 10 grains of quinine was given, and thereafter the symptoms disappeared and the temperature remained normal.

I cannot say with what frequency such gastro-intestinal cases occur; but I had two similar cases when at Bassein.

In this connection it may not be out of place to comment upon intramuscular quinine injections. Since taking over charge in this district I have given over 500 such injections, and in no single case has any untoward result occurred. In some cases female patients will not permit an injection elsewhere than in the arm, and in some

such cases with very high fever I have given injections in this site with no harmful results.

A CASE OF SENSITIVENESS TO MEAT.

By Capt. P. N. MITRA, M.B., D.T.M. (Bengal),

Pasighat, Assam.

S. C. B., Hindu male, aged 38, consulted me on account of his inability to digest meat. He had suffered from this inability since childhood. If he took even a minute quantity of the cooked flesh of goat, sheep or deer, this was shortly followed by an attack of sneezing, difficulty in breathing, tympanites, and finally urticaria. In consequence he shunned meat, and if absolutely obliged to take it took it in very small quantities, ejecting it afterwards by induced vomiting or by taking a large dose of Eno's "Fruit Salt." Riding on a horse or travelling by bullock cart did not produce the symptoms, whilst he could take the flesh of birds and turtle's eggs without ill effect.

On one occasion he took a patent peptone wine,—the peptone of which apparently came from mutton—and the dose was immediately followed by the same train of symptoms. Judging that he was clearly sensitive to some product of peptic digestion of mammalian meat, I proceeded to desensitise him by injections of peptone,—usually prepared from beef. A dose of 0.3 c.c. of a 7.5 per cent. solution was given at first, the dose being gradually raised to 1.5 c.c. of the same solution. Apparently the treatment was a complete success, but will the immunity be permanent?

TWO CASES OF SYNOVITIS TREATED BY INTRAVENOUS IODINE.

By KHAGENDRA NATH CHATTERJEE, M.B.,

Chinsura, Bengal.

SOME time ago, I treated two female patients who were suffering from some obscure form of synovitis, involving many of the joints of the body either simultaneously or one after another, by intravenous injections of iodine. The ætiology of both was obscure, but in one case there was a history of puerperal fever, and both patients had chronic indigestion and aphthous stomatitis. The joints attacked were tender and swollen, the attacks were usually febrile, and the smaller joints were picked out rather than the larger ones.

Assuming that these attacks were the result of septic absorption, I gave intravenous injections of B. P. tincture of iodine, m. 5 to m. 10, diluted with 2 to 3 c.c. of distilled water. After three to four injections the conditions in both cases appeared to be cured. One of these patients has subsequently been under observation for a period of eighteen months, the other for several months after completion of treatment, and both are at present free from a complaint which at one time made their lives miserable.

Indian Medical Gazette.

JANUARY.

MEDICAL EDUCATION IN INDIA.

THE thoughtful and suggestive book by Abraham Flexner of the Rockefeller Foundation shows that systems of medical education are being subjected to a critical study. This was reviewed in the *Indian Medical Gazette* of October 1925. The author writes with special authority as he has made a detailed study of the methods which are employed in the chief countries of Europe and America. It might be expected that a course of education which has been planned by the General Medical Council of Great Britain would be ideal, but it must be remembered that it is impossible for any body of men to work out a scheme of medical education which is divorced from the traditions of the past. Hence it is that our present system represents a modification of the older schemes which grew up from small beginnings in much the same way as a town grows up, and just as the town planner is hampered by the products of the older builders so those who devise modern methods of medical education find it difficult to make a complete break with the past.

It must also be remembered that the regulations of the General Medical Council are not rigid and inelastic decrees so much as a statement of standards which have to be worked up to by those who desire to obtain recognition for their degrees. These standards have been devised with special reference to the conditions which prevail in the United Kingdom, but in spite of the fact that they may not be suitable in all respects to other countries, they have been accepted by Australia, South Africa, Canada, India and other countries. There is obviously a general belief that the advantages which result from uniformity of standards more than compensate the drawbacks following on the adoption of a curriculum which was not devised for the special needs of these distant countries. Even in India, where the conditions of medical practice are so different from those which exist in England, there has never been a general demand for autonomy in the sphere of higher medical education. On the contrary, there has been an insistent demand for the raising of the standards of education in the medical schools so as to bring them into conformity with the requirements of the General Medical Council. It is true that one Indian University has severed its connection with the General Medical Council because of its refusal to permit the representative of the Council to be present at its examinations. There is reason to

believe that this University desires to regain the recognition of its degrees in spite of the freedom which would result from a permanent divorce from the control of a foreign corporation.

The aims of medical education in general can best be stated in the form of replies to the questions which were suggested by Mr. George E. Vincent of the Rockefeller Foundation. These are—

(1) "What kind or kinds of doctors ought the medical schools to turn out in response to the needs and demands of the public?"

(2) "How best can the doctors be helped to master this knowledge and skill?"

(3) "How can they be given the right attitude towards their work?"

It is only by fixing our attention on these questions and by devising a system of medical education which will conform to the spirit that we can hope to solve the problems of medical education in each country.

Systems of education will not work miracles; some of the finest medical men in the world have received the most indifferent education at their schools, while some of the worst doctors have gone through excellent courses of instruction. In the long run it is the men who count rather than the systems: there are many self-made men in the medical world just as there are in business circles.

At the same time it is clear that the efficiency of the average medical man will depend to a large extent on the quality of the training which he has received.

By good training we do not imply a perfect system of coaching and spoon feeding. The most important quality of the medical man is initiative and this is by no means fostered by perfect tuition. A most important part of the training of the doctor consists in forcing him to dig for himself in the fields of knowledge rather than in presenting to him the results of the labours of others. Instruction and guidance are constantly needed, but when the teacher has provided the student with facilities for obtaining his own knowledge he has done all that is desirable, or necessary. The Indian student in particular suffers from an early training which makes him too dependent on the acquisition of knowledge which is dished up for him in an easily assimilated form, he resents being forced to stretch out his hands and seize what he needs.

It is important that the requirements of the general practitioner should be kept in the forefront: medical education is given, for the most part, by specialists, and it is not easy for them to remember that their point of view must necessarily be quite different from that of the average doctor. The student who aims at specializing in some branch should not be allowed to do so until he has laid a broad foundation of knowledge, and undergraduate instruction should consist of teaching what the general practitioner

ought to know of each special branch rather than of educating budding specialists. If a medical curriculum were to be made up by allowing each teacher to devise a course of instruction in his own subject, the result would be a complete and thorough course of training in all the branches of medical knowledge, and Heaven help the unfortunate student who is compelled to go through such a course.

The medical curriculum is now so extensive that the average student cannot possibly satisfy all the requirements of his numerous instructors, new subjects are constantly being added, the older subjects are becoming more and more complex and human capacity is strained to the breaking point.

But while the curriculum badly needs pruning and revision, its defects are by no means insuperable: the good teacher is never a slave to printed regulations and can easily drive a coach and four through the most rigid restrictions. In this respect the examiner must co-operate, for the best efforts of the teacher can be ruined by a bad examiner.

When questions are asked on rare diseases and on matters which are non-essential, the teachers and students are compelled to divert their energies from the things that really matter and the result is that our young graduates too often have a confused smattering of their subjects, instead of having a good grounding in the work of their profession. Examiners have been known to set questions on rare skin and nerve diseases such as the candidate may never see in after life; it is difficult to explain the mentality which prompts such questions, but the results are to make the examinations a hindrance rather than a help in medical education. It is important that examiners should not be hampered in their work by outside interference, but their autocratic position can only be justified by a record of conscientious work on their part. Taking a good broad survey of the whole question, it is obvious that the teachers and examiners count for more in medical education than the details of the curriculum, and even apart from any alteration in the existing regulations, the training of the doctors of the future could be greatly improved if the teachers and examiners were to keep constantly before them the questions which are asked by Mr. Vincent.

Much attention is being paid to the provision of more doctors for medical relief in the villages of India and many suggestions have been made for the solution of this very important problem: under existing conditions the qualified medical man in India cannot obtain a livelihood except in the larger centres of population. It is proposed by some that great numbers of doctors should be turned out, even though the process should result in a lowering of existing standards. By flooding the medical market men will be compelled to settle down in the villages and so their services will be at the disposal of all. This

simple solution has grave defects: it is quite certain that no doctor can obtain a livelihood in the village: the people refuse to pay for his services and so he is compelled to join the great army of medical men who are struggling for existence in the large towns where there is some faint hope of final success and where his children can go to a good school. The only result of the flooding of the market will be to set up a cut-throat competition and to lower the wage-earning capacity of the medical man. Under such conditions the profession will lose its attractions for the young student and the standards of efficiency will inevitably be lowered.

In a recent editorial the proposal to give a smattering of scientific education to practitioners of the old Indian systems was discussed, and this was shown to be fraught with grave danger to the community and to the future of scientific medicine. The chief danger of this proposal lies in the fact that the practitioners of the old systems would advertise themselves as having learned all that scientific medicine has to teach, in addition to the wonderful secrets of their own systems, so that they would claim to be doubly qualified. In time their pretensions would doubtless be exposed, but in the meantime they would reap the harvest that is always at the disposal of those who make the loudest and most insistent claims. If the Government and people of India seriously desire to have an effective system of medical relief there is only one means by which it can be secured, that is by paying for it, by giving an efficient course of medical training to the large number of intelligent young men who clamour for admission to the medical colleges and schools and then subsidizing them so long as they practice in the selected villages, or by opening fresh dispensaries in the places which are not already provided. The idea of obtaining something for nothing is very attractive to individuals and to Governments, but it seldom works out satisfactorily in practice. It is surprising that the medical profession in India has had so little to say about the various schemes which have been proposed with a view to securing their services for nothing: their interests are at stake and it is essential that they should express their views. They may do so with all the greater force as this is a case in which the interests of the community are the same as those of the doctors. India needs good doctors, and these like most other good articles are the cheapest in the long run. India is far too poor to afford badly trained medical men and it is to be hoped that she will not be guilty of the extravagance which is involved in the education of inefficient doctors and public health workers.

A NOTE TO READERS.

The index to Vol. LX, 1925, of the *Indian Medical Gazette* will be published with our issue for February, 1926. It is hoped to publish the review of the Indian medical year, 1925 as a supplement to our issue for March, 1926.

Current Topics.

CORRECTION.

In connection with Colonel Cornwall's letter (published in the December 1925, issue of this Journal) on the subject of the Ayurvedic treatment of rabies, an unfortunate error has occurred and has been overlooked in proof-reading. In line 2 on p. 599, in place of 63 per cent. please read 6.3 per cent.—as the approximate risk run by people in South India of dying from hydrophobia after having been bitten by a supposedly rabid dog.—EDITOR, I.M.G.

The Radium Institute, Ranchi. A Report on the work from 1st April 1925 to 31st December 1924.

By J. C. S. VAUGHAN, M.C.,

LIEUT.-COLONEL, I.M.S., (retd.), 1925.

Patna: Superintendent, Govt. Printing, Bihar and Orissa.

We are glad to welcome this, the first of the series of reports from the new Radium Institute at Ranchi. We presume that this report is by Colonel Vaughan, although, owing to his characteristic modesty, or to an oversight on the part of the official press, his name nowhere appears in it. No price is stated on the cover of the report, but it is issued under official aegis, and we trust that copies will be asked for by all civil surgeons interested in radium work, for it is full of information and instructions as to sending up patients, etc. The work of the Ranchi Institute is too little known in India; it deserves to become known to the whole country.

Colonel Vaughan first started working with radium in 1913, a very small supply having been procured for a special case. Later on, as success with this was maintained, Sir Edward Gait, then Lieutenant-Governor of the province, aided the work with a special grant in 1917. In 1920 a scheme was put up for the establishment of this Institute, which led to its opening in 1922.

The Institute provides three furnished quarters for Indians, each containing three living rooms; also six similar unfurnished quarters for Indians, of which three are reserved for poor patients unable to pay fees. There are also quarters for European patients. Patients can also be treated at the Institute, though not in residence there. The fees charged are:—(a) furnished Indian quarters, Rs. 2 per day; (b) furnished European quarters, Rs. 4 per day; (c) unfurnished Indian quarters, Re. 1 per day; which fees do not include the cost of diet or of servants; for the application of radium Rs. 20 per application, except for patients in the free quarters; for visits to paying patients in the quarters, Rs. 5 per visit; for visits to those outside, the usual professional fees. Officers sending patients to the Institute should be careful to note several points; first, the accommodation is very limited, and no patient should be sent without arrangements having been made beforehand; secondly, full notes as to the history of the patient and the treatment given must accompany the application, as in the absence of such information, it cannot even be stated whether the case is one suitable for admission or not; thirdly, there is no hospital accommodation at the Institute in the usually accepted sense of the term; and previous arrangements must be made for the patient's residence and dieting; servants, friends, etc. In brief the medical officer, before sending up any patient for treatment, would be well advised to write fully to the Superintendent in charge.

At present treatment is entirely by irradiation from radium salts in sealed containers which cannot be sent out of Ranchi, and radium emanation treatment is not available. The tubes used contain radium sulphate in varying quantities, with one special eyelid applicator containing the equivalent of 7 mgms. of radium bromide.

On pp. 4 to 7 of the report, Colonel Vaughan deals with the general principles of radium therapy, a section

which should be read by every medical man sending up patients. Very important is the fact that radium therapy is absolutely contra-indicated in vaginal and uterine cases with recent or present or chronic inflammation of the adnexa; also the value of irradiation as a prophylactic before and after surgical removal of carcinoma.

In all 534 patients were treated at the Institute during the period under review, and the lessons learnt and experience acquired are already of great value, with special reference to Indian conditions. In general it may be said that radium provides the treatment of first choice in such conditions as leucoplakia, keloids, vascular naevi, rodent ulcer, and epitheliomata of all kinds, especially when in the premetastatic stage, or where situated where surgical operation involves obvious scarring and much inconvenient loss of tissue. It now holds an undisputed place in inoperable cancer, wherever situated, alleviating suffering, adding perhaps years to the patient's life, and in some cases "banishing all evidence of the disease for as long as our experience with radium has extended."

The indications for radium treatment may be generally summarised as follows:—

(1) Cases in which cure in non-malignant conditions, or in conditions clinically free from malignancy, may be looked for or even reasonably anticipated. These include eczema of various types, keloids, papillomata, keratomata, corns, rodent ulcer, lymphosarcoma, non-malignant hæmorrhages from the uterus, and small fibroids.

(2) Cases in which great benefit may be expected, both local and symptomatic. These include psoriasis, xanthelasma, capillary naevi, lupus vulgaris and lupus erythematosus, tubercular adenitis, vicious cicatrices, Dupuytren's contracture in its early stages, exophthalmic and parenchymatous goitre, leucocythemia, lymphadenoma, mediastinal tumours; epitheliomata of the skin, cornea, vagina, and urethra; carcinomata of the breast, uterus, bladder, prostate and thyroid; sarcomata, excluding endosteal cases; endotheliomata; early cases of arthritis deformans; and larger uterine fibroids.

(3) Cases where the result is doubtful; such as pruritus, neuralgia, neuritis; epitheliomata of the tongue, mouth, fauces, larynx and œsophagus; carcinomata of the stomach, intestine and rectum; myelomata; melanomata, and glycosuria.

(4) Cases where the treatment is practically certain to be useless; such as the later stages of Dupuytren's contracture, kraurosis vulvæ, adenomatous goitre, osteitis deformans, acromegaly, lipomata, enchondromata, endosteal sarcoma, syphilis, sclerotic diseases of the spinal cord and paralysis agitans.

The bulk of the work hitherto has naturally been on cases of malignant disease, and especially of carcinoma of the uterus and vagina. Here, Colonel Vaughan quotes from Louis Frank as follows:—

(1) Cancer of the uterine body; treatment by total ablation of the tubes, ovaries and uterus yields curative results which we cannot hope to surpass by any other form of treatment.

(2) Early carcinoma of the cervix; the radical operation constitutes a justifiable procedure, but equally good or better results can be obtained with radium, especially considering the mortality of the operation.

(3) All border-line cases should be treated with radium.

(4) Late cases may be improved and palliated by radium as by no other means within our command.

(5) If the five-year period of curability be accepted as indicating a "cure," then the results of radium treatment surpass by far those obtained by the profession at large in the treatment of cancer of the cervix uteri by surgical means.

Practitioners sending up for treatment cases of uterine hæmorrhage should submit the patient in competent hands to a thorough curetting and the curettings should be examined and reported on by a fully competent pathological laboratory beforehand. No case of

fibroid of the uterus should be sent for treatment in which there is evidence of pelvic or adnexal inflammatory trouble.

As might be expected, so far the Institute has been seriously hampered by the admission of late and hopeless cases. The Indian patient tends to try medicine last and surgery later,—if the phrase may be permitted.

The new Institute at Ranchi is doing excellent work, and Colonel Vaughan is to be congratulated on his first report. We may perhaps be permitted to advise that this report, either as a reprint, or re-edited as a brochure, should be made available for wide distribution; on the lines of the well known brochures of the different Pasteur institutes in India, with full and detailed instructions to medical practitioners and patients. "Our existence is only known at present to a comparatively few," writes Colonel Vaughan, "and experience of what can be done and is being done with radium is personally known to only a comparatively small section of the profession in India." We would especially draw the attention of our readers to the facilities provided at the new institute, the first—but not, we hope, the last—of its kind in India. Its record up to date has been one of unostentatious, but none the less valuable work.

Serological Observations on Relapsing Fever in Madras.

A VERY striking paper on this subject was read before the Royal Society of Tropical Medicine and Hygiene on the 21st May, 1925, by Lieutenant-Colonel J. Cunningham, I.M.S., Director of the King Institute, Guindy, Madras, and is reported in the *Transactions of the Society*, Vol. XIX, No. 1.

What is the mechanism of relapses in relapsing fevers? Two views in general have been held; the exact periodicity of the attacks and the observation of granule shedding by the spirochaetes have led some observers to believe that the spirochaetes undergo a life-cycle in the body; on the other hand the presence of antibodies in the serum of infected individuals has led to a belief that the cyclical disappearance of the spirochaetes from the peripheral blood is due to accumulation of such antibodies, and their re-appearance to the diminution of antibodies. In general the Indian strain of relapsing fever shews only one relapse, as observed in 57 per cent. of experimentally infected animals. Only one monkey out of 168 and one squirrel out of some 700 had shewn a second relapse.

The author had worked with three human strains, one from Tanjore, one from Bombay and one from Madras city. The strains were kept alive by repeated passage through animals, at first monkeys, later ordinary Madras squirrels, which had been found to be perfect experimental animals for the purpose. The agglutination reactions of the spirochaetes were carefully tested throughout the infections. His conclusions were as follows:—

1. In experimental infections in animals, the spirochaetes present during the first attack were found to be entirely different and distinct from those present during the first relapse. Serologically two quite different types occurred.

2. The difference between the two types of spirochaete is quite definite. No trace of any group reaction, such as is found in other well-known groups of organisms, could be detected.

3. This serological change of type is unaccompanied by any obvious alteration in the morphology of the spirochaetes. Minor morphological distinctions have still to be investigated.

4. As far as the Indian type of the disease is concerned, i.e., a disease commonly limited to a first attack and one relapse, only two serological types of spirochaete have so far been implicated. On sub-passage these two types alternate regularly. The serological mutation is freely reversible and prevents a multiplicity of types from occurring in nature. Material for the investigation of the mechanism of second relapses was almost entirely wanting.

5. These serological types are permanent and remain

constant on sub-passage as long as the sub-passage is made during the first attack. Once a relapse has supervened, the type changes.

6. Experiments with other strains of *Spirochaeta carteri* and with human sera indicate that this process holds good in natural infections also.

Thus whilst morphologically the spirochaete of Indian relapsing fever is constant in type, serologically the spirochaete present in the febrile relapse is entirely different from that present in the first attack of fever. In general the type of spirochaete present in the first attack of fever is of the "A" or first attack type; exceptionally however it may be of "B" or first relapse type, so that apparently initial infections with the relapse type of spirochaete may occur in nature.

What is the explanation of this extraordinary mutation of type of the infective spirochaete in a disease which is undoubtedly a single entity? Are two types of spirochaete injected into man by the louse, one causing the first febrile attack, the other lagging in development and causing the first relapse? The regular alternation of strains on sub-passage seems to negative this view. Or is the disease due to a single strain spirochaete which has the power of undergoing complete serological mutation under the influence of antibody formation?

Colonel Cunningham's paper was illustrated by beautiful photo-micrographs of the agglutination reactions, and it is one which will give serologists and bacteriologists furiously to think. The serological reactions of any particular micro-organism have been regarded as the most constant and distinctive of its characteristics. For example cholera-like vibrios are constantly found in close association with cholera epidemics; and it is customary to differentiate them from the true cholera vibrio by their serological reactions. Yet Greig has shewn that the proportion of such cholera-like vibrios found increases towards the decline of a cholera epidemic. Can such vibrios be mutation strains of the true cholera vibrio?

Dr. Ledingham, in commenting on the paper, pointed out that at present the data available with regard to mutation on the part of bacteria are too scanty to permit of drawing any definite conclusions. "I do not think the time has yet arrived when we can explain with satisfaction the interactions between parasite and host, but there is no doubt that mutation of bacteria, as now studied in the laboratory, is going to throw a flood of light on the immunological responses observed in the infected patient." There are laboratory parallels to Colonel Cunningham's spirochaete findings in the H and O variants and the S and R variants in the *Salmonella*, dysentery and other groups of bacteria. The presence in the same epidemic of different strains of meningococci and pneumococci may be instances of related phenomena. Dr. Wenyon suggested that possibly the spirochaetes which initiated the disease might be held to divide at first into two types,—types A and B. Type A might cause the first febrile attack, and then disappear as antibodies against type A accumulated; whereas such antibodies might not affect type B, which would multiply and produce the first febrile relapse, whereupon antibodies to type B would appear. Dr. Manson-Bahr drew attention to the extraordinary variation in the virulence of relapsing fevers in different countries. Associated with this was the fact that the disease was tick-borne in some countries and louse-borne in others. Could one and the same organism become modified in its virulence by being transmitted by different arthropod hosts?

Colonel Cunningham's preliminary paper raises so many and such important matters of interest that we look forward to its promised amplification and continuation in the *Indian Journal of Medical Research*.

The Cinchona Alkaloids in Malaria.

AN exceedingly interesting and important discussion on this subject took place at the meeting on January 15th, 1925 of the Royal Society of Tropical Medicine

and Hygiene, and is reported in the *Transactions of the Society*, Vol. XVIII, No. 7.

The subject was introduced by Lieutenant-Colonel A. T. Gage, C.I.E., M.B., I.M.S. (retd.)—formerly Superintendent of the Royal Botanical Gardens, Calcutta, and now Librarian to the Linnean Society. The quina-quina bark originally used in 1638 in the illness of the Countess of Cinchon was that of *Cinchona officinalis*, as the species was subsequently named by Linneus in the following century. Reckless exploitation of this species in the Andes, however, led to the importation into Europe at the end of the 18th and beginning of the 19th centuries of other species; in the long run the three survivors were *C. officinalis*, *C. succirubra* and *C. calisaya*. In 1820 quinine was first isolated, whereas the other alkaloids of cinchona were not differentiated until some thirty years later. As it was found that quinine was of approximately equal potency to the crude bark, its additional æsthetic and pharmaceutical properties gave it an overwhelming advantage, and quinine became the sole and standard remedy for the treatment of malaria.

So far all the bark required had been imported from South America; but by the middle of the 19th century the reckless exploitation of this source of supply led the British and Dutch governments to seriously consider the position. In India the species introduced about the 'sixties of the last century was almost exclusively *C. succirubra*,—a species much poorer in quinine content than *C. officinalis* and *C. calisaya*. The poorness of the quinine yield from this species led to anxiety on the part of the Indian Government, and in 1865 to the appointment of three Commissions in the presidencies of Bengal, Bombay and Madras, to investigate the relative therapeutic value of the different cinchona alkaloids. As the malarial parasites were not discovered until 1881-1890, the trials carried out were purely clinical, and could not be controlled by microscopic examinations.

Of the three Commissions, the Madras one reported most fully. They treated over 1,100 cases in 1866 and nearly 2,500 cases in 1867. They concluded that "beyond doubt ordinary quinine sulphate, chemically pure quinine sulphate, and quinidine sulphate possessed equal febrifugal power; that cinchonidine sulphate was only slightly less efficacious; and that cinchonine sulphate, though considerably inferior to the other alkaloids, was notwithstanding a valuable remedial agent in fever." The other two Commissions reached practically identical conclusions.

The Indian Government now adopted the policy of officially encouraging the use of the alkaloids other than quinine. In 1875 the Madras Government was called upon to explain to the Secretary of State for India why, despite these orders, quinine was being used. Their reply is interesting; it was to the effect that owing to the great value of quinidine and cinchonidine therapeutically the price of both these alkaloids, at £4 per lb. was considerably higher than that of quinine, at £3 4s. per lb. In other words quinine was being used because it was cheaper.

In 1873 sufficient *C. succirubra* bark, grown in India, was available to supply cinchona febrifuge (total alkaloids) for clinical test, and in that year 1,000 cases were experimentally treated with the febrifuge containing the total alkaloids. It was reported that cinchona febrifuge was of equal potency to that of the isolated alkaloids and that it could be sold at Re. 1 per oz.

In the meantime the Dutch had gone ahead with great thoroughness. Selecting the quinine-yielding species for their Java plantations, their output had grown to such an extent that the price of quinine fell from £1 per oz. in 1878 to less than £1 per lb. in 1890. The *Cinchona* species rich in quinine were introduced more and more into the Indian plantations. Cinchona febrifuge of those days "rather resembled powdered bathbrick"; quinine was a clean white crystalline powder; and—accordingly—quinine again pre-

vailed. By 1903 the Indian bark was being used for the extraction of quinine rather than for the production of cinchona febrifuge, and the composition of Indian cinchona febrifuge in 1922 was as follows:—

Quinine	..	10.5
Cinchonidine	..	7
Quinidine	..	16
Cinchonine	..	23
Amorphous alkaloid	..	33
Non-alkaloid	..	1.5
Insoluble	..	3
Water	..	6 parts per 100.

The influence of these various factors increased the sale of quinine and steadily reduced the sale of cinchona febrifuge, which fell at the Bengal factory from 11,000 lbs. in 1881 to 1,600 lbs. only in 1912. With the war the demand for quinine and cinchona febrifuge greatly exceeded the possible supply, and the price of quinine again rose steeply.

Thus the universal use of quinine in malaria in medical practice to-day is the result of many different causes, only one of which is its therapeutic efficacy. Let us now take a detached view of the situation, counsels Colonel Gage. If we could take a bird's-eye view of the immense malarial tracts of this planet, what should we see? "We see a very small number of patients in comfortable circumstances, who can command the service of skilled physicians and nurses, and for whom the cost of a remedy is of no importance. We see a small number of sufferers in civil and military hospitals, who also have at their service skilled attendants and may have a choice of alkaloids. But far exceeding these, so to speak selected cases, we see a vast multitude of human beings who live on continuous sufferance of the pestiferous mosquito, who may ever see a hospital or a medical man, and to whom the Cinchona alkaloids are unknown or unobtainable at a price within their scanty means." For the first two classes we may prescribe the alkaloid of election, for the great mass of malaria-stricken humanity other factors come into play. "Until it is accepted beyond all doubt that one particular alkaloid or combination of alkaloids is so far superior to any others in the treatment of attacks of any kind of malaria as to exclude consideration of the others, then the fittest alkaloid or combination of alkaloids for the overwhelming mass of sufferers will be that which can be produced in the greatest abundance at the least possible cost; can be distributed at the least possible price; and can be used with the least possible medical supervision." But the medical profession has demanded quinine, and Cinchona growers and chemists have adapted their plant and plants accordingly.

If it be proposed to replace quinine with—for instance—quinidine what will happen? In the bark of *C. ledgeriana* and of its hybrid with *C. succirubra* quinidine only constitutes some 7.5 per cent. of the total alkaloids. To replace quinine by quinidine, weight for weight, about five times as much bark will have to be used and the price of quinidine may well rise to heights at present undreamt of. Or else selected species of *Cinchona* rich in quinidine will have to be planted, will have to mature over several years before they can be utilised, and, in the meantime "it may be doubted whether happy expectation would correctly describe the condition either of the Cinchona industry, or of the medical profession, or of the malaria-ridden community."

From the botanical and commercial points of view, therefore, Colonel Gage concludes that quinine should remain the alkaloid of election, unless there are overwhelming therapeutical reasons for replacing it. But for the masses there is no reason why the limited and costly supplies of quinine should not be supplemented on a large scale by the re-introduction of the original cinchona febrifuge, i.e., of the febrifuge containing the total alkaloids of *C. succirubra*.

It will be seen that Colonel Gage's paper is a very important and thoughtful contribution to one of the

most difficult medical problems in India. It was followed by a paper rich in wit and wisdom by Lieutenant-Colonel Clayton Lane, I.M.S. (ret'd.).

How does quinine act? No one knows. From 35 to 93 per cent. of it disappears after administration without trace, metabolised in the liver, intestines and kidneys. After an intravenous injection of quinine there is only some 10 to 15 per cent. of the injected dose still in the circulating blood one minute later. Bass found that malarial parasites were killed *in vitro* in a dilution of 1 in 2,666; corresponding to the oral administration of 30 grains in man; yet this strength is from 50 to 150 times greater than the concentration needed in the blood *in vivo* to effect a cure. The evidence is still confused, but its general trend is to shew that, instead of quinine exerting a direct plasmodicidal effect upon the parasites, it acts indirectly through some metabolic mechanism of the body.

Further where does quinine act? No one knows. Does it affect only parasites which are extra-cellular or those which are intra-cellular, or both? The answer is a confession of ignorance.

What is the best salt of quinine to use? No one knows. Most practitioners prefer the freely soluble salts for oral administration, yet the general evidence is that quinine is not absorbed from the stomach but from the small intestine, and that, whatever form be administered by the mouth, it is first converted into quinine base before absorption. But if it be not quinine itself but a quinine-metabolite that kills the parasites, the matter is rendered still more complicated. Perhaps quinine when administered orally is a protoplasmic poison; it is partly destroyed in the small intestine, such of it as escapes such destruction being destroyed in the liver, and the kidneys flinging out of the body such quinine as the metabolic processes have failed to destroy. An incidental result of this process of destruction may be the production of a quinine-metabolite which destroys the malarial parasites.

Leading French writers have for years been ardently advocating the hydrochloride owing to its solubility, yet in Algeria the official State issue is now as tablets of quinine sulphate. This naturally leads up to the tablet conundrum. Are sugar-coated tablets reliable or not? There seems to be considerable difference of opinion.

Is intramuscular quinine injection a dangerous procedure? The *Lancet* in an editorial considered that the only condition contra-indicating intramuscular injection in practice is debility. Yet there is no reason for thinking that MacGilchrist's guinea-pigs (or Acton's and Chopra's rabbits) were debilitated, and there is clearly more behind necrosis than that. "It is undoubtedly possible to push into a patient with a syringe a lasting conviction that if it has to come to a choice between a bitter taste and a bitterly painful experience, it is better to take quinine by the mouth after all."

Why is primary malaria so easy to cure, and old standing malaria so difficult to eradicate? We need information badly. The whole trend of recent evidence shews that the primary attack of malaria experimentally induced for therapeutic purposes in a general paralytic yields promptly and rapidly to treatment, whereas naturally acquired malaria in the tropics is often very difficult to treat.

Does the season of the year affect the efficacy of quinine treatment? There seems to be some evidence that it does.

At what times should quinine be administered? There is no settled answer. If quinine acts by directly killing the merozoites set free into the blood on rupture of the malarial schizont, then we must aim at having a maximum concentration of quinine in the blood at the time when the merozoites are set free;—the old established view. But if it is not quinine but a quinine-metabolite that acts, then we may require a continuous supply at a low concentration, rather than an intermittent high concentration.

Finally, concludes Colonel Lane, the case for quinine *versus* quinidine is not yet fully proved, whilst apart from the commercial disturbance which might ensue if quinidine were to replace quinine, there is risk that if the available supplies of quinidine are to be used up for treating malarial patients, sufficient will not be available for those cardiac cases for whom it is perhaps essential.

The discussion which followed the papers by Colonel Gage and Colonel Lane was full of interest. Mr. Bernard Howard spoke as a chemist. In general he had found the sugar-coated tablets produced by English manufacturers soluble and satisfactory. The case was very different with samples of tablets from the Indian market; they might consist of anything,—apparently even of concrete. With regard to Colonel Gage's historical summary there was one omission. In 1876 the question came before the Dutch Government as to whether the use of a cinchona febrifuge containing the total alkaloids might not be an improvement upon the extraction and use of quinine. Dr. de Vrij's report on this matter shewed that the febrifuge shewed such enormous variations in composition that the official decision was come to to try and increase the production of quinine and reduce its price rather than to fall back upon the febrifuge. Samples of Indian febrifuge which he had analysed also shewed considerable variation. Speaking as a chemist he considered that a return to the febrifuge would be a mistake. The chemists were aiming at increased purity of quinine and reduction of cost. The moment febrifuge was thrown upon the market as an unstandardised product, the road was open for adulteration. "As a chemist I feel bound to protest against the alkaloids being jumbled up again, and also against the possibility of the most abominable adulteration among certain of the native houses in India, because I have had painful experience of what certain unscrupulous Indian druggists can do if they have the chance."

Sir David Prain spoke of old days in India when "one did not make suggestions to officers in one's medical service older than oneself." Matters to-day were apparently different. Twenty-five years ago he used to ask medical officers in India of his own standing in the service how much quinine they supposed that the human system could assimilate. The answer was "What does it matter, so long as we give sufficient?" But, as he had had to provide the quinine, and as he regarded every grain given in excess of what was required as a grain wasted, he had given serious consideration to the question. He entirely concurred with Colonel Gage in desiring to see cinchona febrifuge more widely used. The amorphous alkaloid contents had always interested him. In India in the old days the officers of the medical services demanded and got quinine; but the planters and missionaries, to whom economy was an object, wanted febrifuge for their servants and clientele. At first febrifuge containing the total alkaloids was issued; and planters and missionaries alike spoke highly of it. Then residual alkaloid (total alkaloid *sine* quinine) was issued; planters and missionaries reported that they much preferred this product to the former one. Next the cinchonidine was taken out; so that the febrifuge issued was *sine* quinine and *sine* cinchonidine; this was issued only to missionaries (presumably because it was the cheapest of the three?). They reported that it was 100 per cent. more efficacious than the previous supply. In fact they preferred a product rich in amorphous alkaloids.

At one time he regarded the introduction of the quinine tablet as "one of the most dangerous things that could be done by pharmacy." "Fortunately for India the fate of the quinine which the pharmacist who offers and the physician who prescribes in tablet form endeavour between them to lose, is determined not by them but by the Indian conservancy attendant,—in this, as in much else,—an artist in his craft."

Professor Swellengrebel referred to sugar-coated quinine tablets of Italian manufacture. Several hours'

immersion of these tablets in water had left them unaffected, although they were of recent manufacture and perfectly fresh. After twelve hours the sugar coating had been partly dissolved and some of the quinine had been dissolved, but part of it was still adherent to the undissolved coating. He agreed entirely with Colonel Clayton Lane as to the undesirability of intramuscular quinine; during the 1924 epidemic in Russia they had been forced to give quinine intramuscularly, not for its better therapeutic effect by this route, but for economic reasons. His experience in the treatment of general paralysis of the insane by experimentally induced malaria had been the same as that of previous speakers; the malaria so induced was exceedingly amenable to treatment.

Dr. H. A. D. Jowett, speaking as a chemist, advocated sugar-coated tablets of the neutral salts in preference to others. Some of the French tablets which he had examined appeared to be entirely coated with French chalk instead of sugar. "French chalk is very good for polishing a ballroom floor, but I am not aware that it is satisfactory therapeutically." It was very easy to test a sugar-coated tablet for solubility; it should be placed in water in a test-tube and kept at body temperature and from time to time gently shaken; the sugar coating should then dissolve without residue.

Dr. W. H. Martindale considered that it should be possible to determine whether the active agent in quinine therapy was the quinine itself or a quinine-metabolite; experimental testing of the blood should determine it. Quinine base administered orally in salol or stearine-coated tablets, was as efficacious as any quinine salt. He did not see the point of sugar-coated tablets. "Someone found a tablet which was indifferent to acids, and even to striking with a hammer. That, I think, was a French make, not a British product."

If 5 or 8 grains of quinine salt in relatively concentrated solution were added to a volume of 1 or 2 per cent. sodium bicarbonate solution (representing the body fluids) you got an extraordinary coagulum of dense white precipitate of quinine base. Could one imagine anything more unsatisfactory for intramuscular injection than such a mess? Dr. Wenyon had spoken to him of having had to "carve quinine out of the tissues after injections of it have been given." Surely some form of quinine more suitable than an acid salt could be found for intramuscular use.

Sir Leonard Rogers said that a study of the records shewed that James Lind in 1765 had treated 400 cases of remittent malaria in Bengal with 2-gramme doses of cinchona bark with complete success. In general he advocated quinine for oral use, the intramuscular use of cinchonine bihydrochloride and the intravenous use of soluble quinine salts being reserved for special cases. Sir Harry Waters said that on his railway he had been forced to abandon the use of cinchona febrifuge tablets. They had persisted in trying them for two years but had had to go back to quinine, as those taking the febrifuge were incapacitated from severe headache.

In replying to Mr. Howard's remarks, Colonel Gage said that he advocated the use of cinchona febrifuge to supplement, not to replace the use of quinine. The risks of variation of composition and of adulteration would have to be faced. Quinine itself was frequently adulterated; he had found spurious tablets being sold in Bengal which contained only a quarter of a grain or even none at all. He had often heard of nausea as following the use of cinchona febrifuge, but never before of headache severe enough to necessitate stoppage of work.

It will be seen that this symposium of opinions by a gathering of eminent authorities leaves the question of the best method of treating chronic and relapsing malaria still unsolved.

Rectal Injections of Quinine.

THE value of rectal injections of quinine has been a subject of so much dispute that it is interesting to read an account of the careful experimental work done by

Dr. William Fletcher of Kuala Lumpur. The results are concisely stated in the following summary.

"In the year 1923 we published an account of the unsatisfactory results which follow rectal injections of quinine, and of the pain and tenesmus which they sometimes cause. Our conclusions were greatly at variance with established opinion and, in consequence, the Medical Research Council and the Medical and Sanitary Advisory Committee of the Colonial Office asked that further investigations should be made.

(a) First, we gave injections to guinea-pigs. These were returned too quickly to allow satisfactory absorption of quinine to take place.

(b) Secondly, we gave a series of rectal injections, two each day for at least six days, to a couple of groups of men infected with malaria. The first group, consisting of ten patients, received 20 grains of quinine bihydrochloride, dissolved in 4 ounces of salt solution, at each injection. The second group, which comprised six men, received the same quantity of quinine, but it was dissolved in 8 ounces of saline, instead of 4 ounces.

In the first group, out of seventy-one injections, sixty-one were returned during the first twenty minutes; none was retained permanently; the average time of retention was thirteen minutes. Quinine was found in the urine after only thirty-six out of 132 injections.

In the second group, out of thirty-two injections in which the time was noted, three were retained permanently and the average time of retention, for the remaining twenty-nine, was seventeen minutes. Twenty-five were returned within twenty minutes. Quinine was found in the urine after thirty-three out of fifty-seven injections. In many of the cases where quinine was present the amount was very small. When 10 grains, twice a day, were given by the mouth, instead of 20 grains by the rectum, abundant quinine appeared in the urine.

(c) In eleven out of the sixteen cases of malaria in the two groups, 40 grains of quinine bihydrochloride, given daily *per rectum*, failed to get rid of asexual parasites within a week. Quinine was then administered to these patients by the mouth, with the result that the parasites quickly disappeared.

(d) Rectal injections, containing $2\frac{1}{2}$ grains and 5 grains to the ounce, were given to a healthy European but he was unable to retain them for more than ten or fifteen minutes, and the absorption from 60 grains injected into the rectum appeared to be inferior to the absorption from $2\frac{1}{2}$ grains given by the mouth.

(e) The presence of mucus and membranous shreds, passed by patients undergoing treatment with rectal injections of quinine, demonstrates the irritating action of the drug upon the mucous membrane.

Final Conclusion.—In view of these results we reiterate our former conclusion (Fletcher, 1923) that "quinine is too irritating for administration *per rectum*. It should not be given by this route if any other means are available."

Malarial Infection as it occurs in Late Pregnancy: Its Relationship to Labour and Early Infancy.

By Drs. D. B. BLACKLOCK and R. M. GORDON.
Annals of Trop. Med. and Parasit., 1925, Vol. XIX,
No. 3, Sept., 30th, p. 327.

THIS paper is an extremely important contribution to our knowledge of the pathology and epidemiology of malaria; in fact it is not too much to say that it should be read in detail in the original by every medical man working in an area where malaria is rife among the female population of the locality. Further, the beautiful colour plates with which it is illustrated will be invaluable to the laboratory worker.

Working in Sierra Leone, the authors shew that malarial infection of the placenta in women in confinement is very common; it occurs in some 36 per cent. of cases—an enormously high percentage. The prevalent type of infection is with the parasite of malignant tertian malaria.

In spite of this fact, however, infections demonstrable in the peripheral blood are in comparison few, not only among women in labour, but also in non-parturient women, adult males, and even in children. This difference between the intense infection of the placenta and the relative infrequency of parasites in the peripheral blood the authors attribute to a relative immunity of the peripheral blood (in malignant tertian infections).

Gametocyte production is not observed in the infected placenta; these women do not constitute a danger to the community so far as the spread of malaria is concerned. Further, pathological effects upon the mother may be lacking; she may be in relatively good health.

Amongst the infants born of such infected mothers, some may be born healthy, may survive and shew but little ill effect. On the other hand the series observed contains proof of a very complete association between maternal infection with malaria in the placenta, and death of the child either *in utero*, or within 7 days of birth.

Congenital infection of the child direct from its mother and from the infected placenta is very rare, if indeed it occurs at all it is probably due to accidental tears or ruptures of the placenta permitting parasites to pass through into the foetal circulation. (That congenital malaria does occur—although perhaps very exceptionally indeed—is shown by several instances quoted in the literature of recent years.)

What does occur is not congenital malarial infection of the foetus *in utero*, but its death from malnutrition or from toxæmia. Toxic substances appear to be absorbed by the child from the intensely infected placenta of the mother, whilst so enormous a proportion of the red blood corpuscles in the placental circulation of the mother is destroyed by the parasites, that the nutrition of the foetus is gravely interfered with.

We have seen of recent years scarcely any paper on the subject which brings home to us more clearly the sequence of the events in and the pathology of malaria in advanced pregnancy. We gain a vastly interesting and very informative picture of the maternal circulation in the placenta blocked and partially paralysed by massive malarial infection; of the foetal placental circulation, not indeed infected with malarial parasites, but deprived of necessary nutrition, with the consequence of foetal deaths, still-births, and deaths within the first week of life. Early infant mortality in malaria infested districts in the tropics is enormous; is this pathological picture representative of a very important factor in its causation?

The authors are to be warmly congratulated upon a most important and most informative contribution to the question of the role of malaria in maternal and foetal mortality.

The Transmission of Oriental Sore by Sandflies.

A FURTHER contribution to this interesting problem appears from Drs. S. Adler and O. Theodor in the *Annals of Tropical Medicine and Parasitology* for 1925, Vol. XIX, No. 3, p. 365.

In Palestine the epidemiological evidence in favour of the transmission of oriental sore by the sandfly *Phlebotomus papatasi* has so far been ambiguous, but rather in its favour. In the village of Artuf oriental sore was first found in 10 patients by Dostrowsky early in 1925. The population of the village consists of 114 souls and in 1923 the local physician, Dr. Jaruslawsky had noticed the absence of sandflies in the village. That summer however sandflies became a perfect pest in the village. In June 1924 *Phlebotomi* were found in every house, the species present being *P. papatasi*, *P. minutus*, and *P. perniciosus*, the first in overwhelming numbers.

In October 1924 the authors commenced an examination of *P. papatasi* captured in the wild state in Jericho, the reputed endemic centre of oriental sore in Palestine. Of 175 females dissected during the months of October to December, 3 shewed motile *Herpetomonas* in their

mid-gut. In June 1925 a batch of 175 female *P. papatasi* from the same source was dissected. In one typical herpetomonad flagellates were found in the mid-gut, where swarms of them appeared to be attached to the posterior surface of the oesophageal valve, and others in the oesophageal diverticulum. The thin-walled oesophageal diverticulum in *Phlebotomus* is an important structure, since in fresh dissections waves of peristalsis can be seen to pass along it propelling its contents into the pharynx and buccal cavity, upon which it practically opens.

Permanent stained preparations were made from the contents of the diverticulum and the mid-gut behind the oesophageal valve. The remainder of the infected material was inoculated into the forearm of a human volunteer by scarification technique at two points on the 26th June, 1925. On the 31st July, 1925 a small papule was noticed on one of the two inoculation sites, so small that it would ordinarily have passed unnoticed. Films from this nodule shewed typical *L. tropica*. This volunteer had previously been in Mesopotamia from 1917 to 1920 without developing oriental sore, and lived in Jerusalem where the inoculations took place, and where no oriental sore of locally acquired origin has yet been reported. Nothing was noticed at the other site of injection, which was examined with negative results.

(The authors are careful to note that the successful experiment proves nothing more than that herpetomonads collected from an infected sandfly found in the wild state will induce a *Leishmania* papule in man. The question of other possible insect vectors remains for consideration. Yet in view of (1) the evidence given by Acton 1919, in Mesopotamia that the distribution of oriental sores upon the surface of the body corresponds with that of oriental sores; (2) of Patton, 1919, 1922, that *Herpetomonas* is present in *P. papatasi* in Mesopotamia and Palestine; (3) of the Sergeant brothers, Parrot, Donatien and Beguet, 1921, who infected a human volunteer in a non-endemic centre with crushed material obtained from sandflies collected at Biskra, a notoriously infected centre for oriental sore; (4) of the way in which the habits and environment of *P. papatasi*—a sandfly of desert habitat—fit in with the epidemiology of oriental sore; it would appear as if the chain of evidence is almost complete. It would appear that active development of *L. tropica* occurs in the mid-gut of the female *P. papatasi*; that the infection in the fly centres in the anterior end of the mid-gut and especially on the posterior aspect of the oesophageal valve; that the oesophageal diverticulum becomes infected, and that the infection is probably passed back to man when the fly feeds again. Crucial experimental proof, however, is still to be provided. In recent work at the Calcutta School of Tropical Medicine it is interesting to note that locally captured and bred-out females of *P. argentipes*—the possible carrier of kala-azar—have shewn no flagellate infection when fed upon a patient with oriental sore; and that the geographical distribution, habits and habitat of the two sandfly species appear to be entirely different).

The Borocaines, a New Class of Local Anæsthetics.

By A. J. COPELAND, M.A., M.B., D.P.H., B.Sc., and

H. E. F. NOTTON, B.Sc., A.R.C.S.

British Med. J., 26th Sept. 1925, p. 547.

THE disadvantages of cocaine as a local anæsthetic scarcely need to be enumerated; it is toxic, it is expensive, it is apt to lead to the cocaine habit, it may prove irritant. Hence the search for an efficient substitute, free from these disadvantages, goes on. In this article Drs. Copeland and Notton summarise the results of their work with the borocaines, work carried out at Cambridge under the help and advice of Professor W. E. Dixon, F.R.S., and Professor Sir William Pope, F.R.S., on the pharmacological and chemical sides respectively.

It has been shewn that ethocaine hydrochloride (novocaine) has a strong affinity for sensory nerve fibres, but has very little action on sensory nerve fibrils in the eye. When it is dissolved in rabbit or horse serum, or even in a solution of egg white, however, its anæsthetising action is increased some twenty-fold; whilst if the proteins present in the solution be removed by boiling, it can be shewn that this is due to the action of the *alkali* present. In fact in general even with cocaine, the higher the pH, i.e., alkaline content of the solution, the greater the anæsthetising value.

Now the solutions of high pH value differ from those of low or acid pH value chiefly in that in the former hydrolytic dissociation predominates, with the cocaine present as a base; in the latter electrolytic dissociation predominates, with rapid absorption of the anæsthetic into the general circulation. "The action of a local anæsthetic depends upon the specific selective affinity of its *base* for nerve fibrils. But the different salts of such a base vary greatly according to the acid with which they are combined. If they are combined with strong acids—i.e., such as dissociate electrolytically to a large extent,—the salt is relatively rapidly absorbed into the general circulation and is less effective locally,—i.e., its toxicity is relatively high and its anæsthetic action relatively low. On the other hand, if it is combined with a weak acid which does not electrolytically dissociate to any considerable extent, it is relatively slowly absorbed into the general circulation and is more effective locally, i.e., its toxicity is relatively low and its specific anæsthetic efficiency relatively high. Such salts have a high pH value."

From among such compounds with weak acids the compounds with boric acid—the "borocaines"—were finally selected. These appear to fulfil the conditions required. They are much less toxic than the original hydrochlorides, but often exert more than ten times their anæsthetic action. The borate of beta-eucaine is the most powerful borocaine, being more than ten times as efficient as cocaine hydrochloride. Its toxicity has still to be determined.

It is promised at the conclusion of the paper that clinical reports will follow later. Meantime, as it is obviously of the utmost importance that only reliable supplies shall be placed on the market, "for this reason" state the authors, "the manufacture of the borocaines has been entrusted to the British Drug Houses, Ltd., and this firm is prepared to supply the compounds." Borocaine, the present standard product, is the borate of ethocaine, a stable, white, crystalline powder, freely soluble in cold water, Ringer's solution and normal saline. An aqueous solution has a pH of about 8.0 and is well on the alkaline side of neutrality. It is claimed by Copeland and Notton as "an ideal surface anæsthetic, practically without toxicity and non-irritant." For eye work and dental use a 2 per cent. solution is advised; for operations on the nose and throat a 5 per cent. solution. One tablet dissolved in 1 c.c. of distilled water makes a 2 per cent. isotonic solution, and it is issued in tubes of 20 tablets at 1s. 6d. per tube, or 5 tubes for 6s.

The further reports on "Borocaine" will be awaited with interest.

Melioidosis.

A Disease of Rodents Communicable to Man.

By A. T. STANTON, M.D., M.R.C.P., D.P.H.,
and

WILLIAM FLETCHER, M.D.

It is likely that this disease, which was first described by Whitmore in the *Indian Medical Gazette* in 1912, is more common than it is supposed to be. We give a few extracts from a valuable bulletin on the subject by Drs. A. T. Stanton and William Fletcher.

Melioidosis is very like glanders and the true nature of the disease can be determined only by the cultivation of the causative organism from the lesions, or from the blood, sputum or urine.

It was first recognised as a new disease by Whitmore and Krishnaswami (1912). A year later, Whitmore (1913) published an excellent account of the malady under the title of "A Glanders-like Disease Occurring in Rangoon." Knapp (1915) and Krishnaswami (1917) have made further contributions to our knowledge of this subject. Stanton and Fletcher described new forms of the disease and proposed for it the name "melioidosis" as the physicians of ancient Greece had described it by the name "*Melis*"—a variety of conditions resembling glanders; they called the causative organism *Bacterium whitmori*, in order that Colonel Whitmore's name might continue to be associated with the bacillus which he was the first to isolate and describe.

The disease occurred as a severe distemper among laboratory animals at Kuala Lumpur which broke out towards the end of 1913. The initial symptom was a milky discharge from the eyes and nose which was speedily followed by pulmonary involvement and death. Its connexion with Whitmore's bacillus a disease of man was not suspected. In the year 1917 several cases of the infection occurred both in man and animals; they were due to the same bacillus.

The problem of the way in which man contracts melioidosis remains unsolved. A large proportion of the cases observed by Whitmore, Knapp and Krishnaswami were morphia-injectors; at one time they considered that infection was carried by the syringe and they called the disease "Morphia-injectors' Septicæmia"; but none of the cases which have occurred in Kuala Lumpur have been injectors of drugs.

It has been proved experimentally that animals can be infected by feeding, and as the onset of the disease in several human cases has been marked by very severe gastro-intestinal symptoms, it is probable that in man infection takes place through the medium of food which has been contaminated by rats.

The bacillus has been found in the blood, the sputum, the urine and the discharge from the superficial lesions of human cases, and the lungs are almost invariably affected.

Only a small number of cases has been recognised up to the present time; thirty-eight by Whitmore in Rangoon during 1911-1912, one in Singapore in 1922 and eleven in Kuala Lumpur between 1917 and 1924 (four in 1917, one in 1920, three in 1921, two in 1923, one in 1924). Of these fifty patients, twenty-five were Indians, twenty-three were Burmans, one was a Chinese and one a European; with one exception all were males. Some additional cases have been seen by Knapp (1915) and by Krishnaswami (1917) in Rangoon, since the publication of Whitmore's account of the disease in 1913. It is highly improbable that melioidosis is limited to the three towns where its presence has been detected; but its diagnosis is almost impossible in places where there is no laboratory, and even where laboratory facilities are available the disease may escape recognition by those who are unfamiliar with it.

Though the recognised morbidity rate from melioidosis is very low, the case mortality is very high. So far, only two men are known to have recovered from the disease.

ÆTIOLOGY.—*Bacterium whitmori*, the causative organism of melioidosis, possesses marked characteristics which distinguish it clearly from other pathogenic bacteria. Whitmore has described it in detail and in this short account we shall follow him closely.

The bacilli, as seen in films made from the lesions of an infected organ, are about the size and shape of *B. mallei*. They stain readily with all the usual stains; but they are neither acid-fast nor Gram-positive. With Leishman's stain they show a well-marked bipolar staining, a character which is exceedingly useful in arousing early suspicion of the nature of the infection. When a preliminary examination of films from diseased organs is being made. Growth upon all the usual culture media is rapid and luxuriant; it occurs under both aerobic and anaerobic conditions, though much more luxuriantly under the former. On the surface of liquid

media a pellicle is formed which becomes a tough wrinkled skin in the course of four or five days. The two outstanding features of *B. whitmori* are, first, its motility in young cultures and, secondly, its curious growth on glycerine agar. Cultures on agar containing 5 per cent. of glycerine begin to acquire a wrinkled appearance in a couple of days; the growth rapidly extends until after a week's incubation it has become heaped up and rugose like a thick growth of tubercle bacilli.

Animal inoculation.—Rodents are readily infected by feeding, by inhalation, by subcutaneous inoculation and by scarification of the skin. The subcutaneous inoculation of a freshly isolated and virulent culture of *B. whitmori* will cause the death of a guinea-pig, rabbit or rat, from septicæmia in less than twenty-four hours.

MORBID ANATOMY.—The characteristic lesion of melioidosis is a small yellow, caseous nodule which commences as a collection of polynuclear cells surrounded by a zone of congestion. By the time these nodules have become large enough to be visible to the naked eye, they consist of a mass of necrotic, caseous material containing a great number of chromatin fragments which are the remains of dead nuclei. The nodules have been found in almost every part of the body, except the brain, and they coalesce to form large areas of caseation, particularly in the lungs. They sometimes break down to form abscesses, in the viscera of man, but not in animals. Small abscesses are the commonest lesion in the spleen; in the liver larger abscesses are more frequent.

The lungs are nearly always affected. When the disease is not far advanced, the nodules can be felt, like shot, within the substance of the lungs; they resemble miliary tubercles, except that they are less numerous and more scattered. When the process has gone further the lungs may be filled with large caseous masses; nodules in the lungs very rarely break down to form abscesses.

Symptomatology.—Melioidosis presents no cardinal symptoms upon which to base a diagnosis.

When the infection is very virulent the illness begins suddenly with vomiting, collapse and diarrhœa so severe that a tentative diagnosis of cholera has been made on more than one occasion. The four cases which occurred in Kuala Lumpur, during 1917, all began in this way and all were fatal. In these very acute cases a reaction usually occurs, on the third day the temperature rises and assumes a swinging septic character; in one instance, a patient actually died during the stage of collapse, seventy-two hours after the beginning of his illness. When the initial infection is less virulent, there is no preliminary collapse but fever is high from the commencement, and the patient passes quickly into a typhoid condition. If he survive the initial septicæmia, the organisms establish themselves in various parts of the body where they multiply and form caseous or pyæmic foci. There are nearly always some signs of pulmonary involvement and the lungs are found to be diseased in 90 per cent. of the cases examined after death.

To sum up, some of the most acute cases resemble cholera or plague; others, which have a high temperature from the beginning, resemble malaria, enteric fever or general tuberculosis; yet others find their way to the dysentery wards. If pustules and abscesses appear a diagnosis of acute glanders may be made; while the bone lesions which appear later on, resemble tertiary syphilis or chronic tuberculosis. Delirium is a common symptom, and one unfortunate patient was confined in a cell because he was supposed to be afflicted with acute mania.

A certain diagnosis can be made only by cultivation of the causative organism. A "positive" agglutination reaction is of value as presumptive evidence, particularly if the titre of the serum increases after an interval, but this reaction is obviously of little value in the diagnosis of the disease in its more common acute form.

B. whitmori has been cultivated from the blood and urine of human cases and also from pustules and abscesses when these have been present.

In cases of obscure fever, associated with enlargement of the liver, this organ should be explored with a needle and glycerine-agar slopes and animals should be inoculated with material thus obtained. Whenever an abscess of the liver is aspirated or drained, glycerine-agar and guinea-pigs should be inoculated with the pus. Some cases of abscess of the liver due to *B. whitmori* have been mistaken for amœbic lesions.

The Work of the British Social Hygiene Council.

A FRESH advance has been made in the combating of disease which is signalled by the change in title of the National Council for Combating Venereal Disease to that of the British Social Hygiene Council, which met in the Conference Hall at the British Empire Exhibition, Wembley on the 5th October 1925.

The change in title is significant. In 1913, there was a conspiracy of silence as to the mention of venereal disease in any of its forms. To-day venereal disease is no more interesting from a general standpoint than measles or small-pox, but just as small-pox must be attacked by means of vaccination, so venereal disease must be combated by every known weapon in the arsenal of the medical profession.

The change of title means that those who have organised themselves to fight the imperial menace of venereal disease have now reached the second line of trenches. In England there is reason to believe that new cases of syphilis have fallen by nearly fifty per cent., the evidence being that cases of syphilis presenting themselves for free treatment in 1920 numbered 40,000; there were only 23,000 cases in 1923, who so presented themselves in England and Wales.

This result has been obtained by efforts made jointly by the Ministry of Health, the local authorities and the British Social Hygiene Council, which have co-operated to ensure that the infected members of the public should seek and continue the free treatment provided for them. During the last eight years over 15,000 lectures have been delivered and over 3 million persons have been enlightened through the cinema film and the spoken word.

Until quite recently the immediate problem was so serious that little more could be done than present a frontal attack to the disease. It was the policy of free clinics that prevailed but now it has become possible to co-ordinate effort throughout the Empire. England is following the Dominions in the change of title and at last the broad view can be taken that while venereal disease must be treated and combated as vigorously as ever when it appears, the main policy of prevention which has been preached for over a generation by leaders such as Sir Ronald Ross, and many others, can become a definite policy.

What the Council stands for to-day is that every effort shall be made to ensure that general conditions of life shall be so improved that the risks of contracting disease shall be enormously reduced. This is no pious hope but an expression of opinion based on the work accomplished by General Harrington when he took command in Constantinople. By improving conditions, General Harrington reduced the incidence of syphilis by one half in the troops under his command. The view of the British Social Hygiene Council is that in the civilian population the same result can be achieved and there is the belief that other diseases such as tuberculosis will decrease in the same way as syphilis will decrease once social conditions are improved.

The Meeting at Wembley Exhibition means that the British Social Hygiene Council is greatly extending its line of attack. Instead of merely providing help for those who have been victimised it is determined so to organise public life that children will be prevented from ever becoming victims. What has hitherto been

its main objective will be pursued as vigorously as ever. Venereal disease will be attacked wherever it arises, but so much progress has been made in the last years that the Council is now able to supplement its remedial measures by carrying out the ideal which all along it has had in mind of so altering social conditions that there should be no reason for these diseases ever to be contracted.

The interest shewn by India in the work of the Council was shewn at the meeting on the 7th October, 1925, which dealt with the problems of venereal disease in India.

Lord Willingdon, despite the many claims upon his time, has acted for some time past on the India Committee of the British Social Hygiene Council and is now Chairman of what is termed the Imperial and International Questions Committee of that body. In this capacity he has taken a very prominent part in combating venereal disease throughout the Empire, confining his attention more particularly to Bombay and Madras where, as administrator, he had fullest knowledge of the evil which is causing untold suffering, not only throughout the Empire but all over the world.

Knowing from close at hand information the appalling ravages which various diseases make among the people of India, he said to a representative of *Reuter*:

"I welcome the suggestion of becoming Chairman of what was originally the India Committee of the British Social Hygiene Council and which is now developed into the Imperial and International Questions Committee of that body, for it has given me an opportunity of keeping up my interest in the well-being of the people of India. From personal experience, I am fully aware of the magnificent work which is being done by the medical advisers of the Indian Government who prevent disease of all sorts. Scourges such as plague, malaria, cholera and hookworm have already been brought under control and it is not the fault of the medical profession that to-day another disease has not been completely eliminated from the country. Unhappily year by year venereal disease is becoming more prevalent in India, especially in the more commercial rather than industrial centres. I am convinced that two objectives must be borne in mind. The disease must be fought directly wherever it raises its head, but after-conditions must be so improved that the danger of individuals contracting it must be reduced."

"What must be remembered is that the question of venereal disease is one directly affecting the public health and is of equal importance as such terrible scourges as plague, malaria and hookworm. It is perhaps in some ways even more important than these. Despite the work of the British Social Hygiene Council, ignorance still prevails as to the danger incurred. The length of the period of infectivity has led to its becoming widely spread in ignorance and in all innocence, and this directly affects the quality of the succeeding generation. The aim of the British Social Hygiene Council is now twofold. It aims as zealously as ever to seek out and destroy the disease wherever it exists. It has achieved the magnificent result that it now is everyone's opinion that this objective should be worked for, but it has taken an important step further as is signalled by its change of title from the National Council for Combating Venereal Disease to indicate to the public that all classes of venereal disease must be attacked by the same type of method as other diseases must be attacked. This year's meeting at Wembley marks a grand stage in advance. It demonstrates all over the world that the British Social Hygiene Council at any rate recognises that venereal disease can only be eliminated if the general standard of public morals is raised. The mistake must not be made to believe that there is to be any relaxation in the specific frontal attack that has been made and is being made by the Council.

The Council, however, is of opinion that the time has now come when it is desirable greatly to broaden the basis of its attack. Syphilis and gonorrhoea need special machinery for their elimination, but I am convinced

that means adopted to combat them will have their valuable effect on other scourges such as tuberculosis and so forth. While perfect environment does not mean perfect health, improved environment and improved conditions unquestionably lead to a reduction, if not eventually to the elimination, of disease. So far as India is concerned we are at present only in the initial stages. We know that a large amount of the infant mortality from which the provinces suffer is due to infection through venereal disease, and I trust that the coming visit of the small commission of experts which we propose to send under the auspices of our Society will be able to help in giving the best advice as to how to grapple with this problem, in order that we may assist in securing more health and better vitality among succeeding generations in India in the future."

Following the Wembley Congress organised by the British Social Hygiene Council, a meeting was held in Paris of the Union Internationale contre le Peril Venerien where important decisions were taken with a view of further combating venereal disease. Great Britain, France, Germany, the United States of America and twelve other countries were represented by delegates from the recognised Social Hygiene organisations, by delegates from the various National Red Cross Societies and by a number of official Government representatives.

Of the many important decisions reached, the most striking was the unanimous decision that the regulation of prostitution was inconsistent with efforts to eliminate venereal disease. It will be remembered that this same point was brought out so long ago as 1913 at the International Medical Congress held in London. In Paris the system of control of prostitution was condemned purely on medical grounds, thus after 12 years endorsing the decision reached in London. The Congress dealt particularly with the problem of eliminating disease from the mercantile marine, with the measures which should be taken in connection with frontiers, with the problems of prostitution and the problem of the disease in connection with emigration. Apart from the purely medical aspect there was the important advance that certain of the shipping interests agreed cordially to co-operate by financial assistance with the measures recommended in the mercantile marine.

The Technique of Supra-pubic Prostatectomy.

From the clinic of Prof. Hugh Cabot, University of Michigan, Ann Arbor, U. S. A.

By BASIL HUME, M.B. (Lond.), F.R.C.S. (Eng.).
Lancet, May 9th, 1925.

THE general management of cases of supra-pubic prostatectomy has remained almost unchanged in England since the operation was first introduced by Freyer, with the single exception of the modification of the "open operation" described by Sir John Thomson-Walker, and by Judd, of the Mayo Clinic.

Dr. Hume had the good fortune to work for a year with Prof. Cabot.

On admission to hospital bladder drainage is instituted in all cases as a routine measure. This is done either by the indwelling catheter or by supra-pubic cystotomy, and is irrespective of there being urinary infection or marked residual urine.

If the residual urine is infected, but the patient's general condition good and his renal function tests satisfactory, the case is usually a better operative risk than a patient in a similar condition but with uninfected urine, because in the former case he has acquired an active immunity to such organisms throughout his urinary tract.

In Prof. Cabot's clinic two tests of renal function are employed, the blood-urea and the phenolsulphonephthalein. These are considered in conjunction with the general physical condition, the blood pressure, and the volume of urine secreted in relation to the fluid intake in determining the patient's fitness for operation.

The *blood-urea examination* indicates the degree of retention of the nitrogen metabolites; 0.2 per cent. is taken as a normal value and 0.4 per cent. as a high normal.

The *phenolsulphonephthalein estimation* is a test of the efficiency of renal excretion, and was devised by Rowntree and Gerharty. It is based upon the specific selective power of the renal epithelium to excrete even small doses of the dye, and is capable of accurate quantitative estimation. That it has not come into general use in this country may be due to a misconception of the technique. The test is performed as follows:—The patient takes from 200 to 400 c.c. of water half an hour before the test; 1 c.c. of a solution of phenolsulphonephthalein, containing 6 mg. of the dye to the cubic centimetre, is injected intravenously and the time noted. The catheter is allowed to drip into a white kidney basin or a cup containing sodium hydroxide solution and the time of appearance of the dye noted. The urine is then collected in a clean bottle for one hour from the time of appearance (not the time of injection as is sometimes the case) and a further specimen collected for the second hour. Enough sodium hydroxide is added to each specimen to make it strongly pink without precipitating the phosphates. The amount of dye excreted is estimated by comparison with a known standard in a colorimeter. An appearance time of from three to six minutes is normal and a total function for the two hours of 80 per cent. or over. The total function should be at least 50 per cent. before prostatectomy is performed. The appearance time alone does not give any very reliable information. Sometimes a small quantity of dye comes through fairly early in a damaged kidney. When the appearance time is long, but the total function is good, it means that the catheter is not in the lowest point of the bladder, or that a large post-prostatic pouch is present.

A soft, red rubber catheter is introduced and tied into the bladder, the eye being at the lowest point at which it will just run. It is then connected by fine tubing with a bottle attached to the side of the bed.

The catheter is left in until the patient is ready for operation. A few days after its introduction a transient rise of temperature, from 100° to 103°, will occur, and last one or two days. This reaction is an almost constant one, and is due to the production of a mild grade of cystitis. In cases that are drained it is found that the cystitis following prostatectomy is much less marked than in the undrained ones. When the renal function tests are satisfactory such a case is usually ready for operation about one week after the reaction has subsided.

If for any reason the indwelling catheter has to be removed, or if the patient is a poor operative risk, either clinically or by renal function tests, and prolonged drainage is likely to be required, the surgeon should proceed at once to drain the bladder by suprapubic cystostomy.

The bladder is distended in the usual way, and a mid-line incision made commencing one finger-breadth above the upper border of the symphysis pubis. This lower limit should not be transgressed. When the extraperitoneal, or perivesical fat, has been reached, the surgeon when incising or tearing through it should avoid any downward extension, in order not to open the loose cellular tissue of the retro-pubic space of Retzius.

At this stage of the operation the lower limit of the parietal peritoneum will be seen as a fold on the surface of the bladder. It should be pushed upwards and gently stripped from the bladder with the finger. The bladder is next secured with tenaculum forceps or retaining sutures and incised in a vertical direction as high up as possible. The bladder is explored with the finger and the condition of the prostate investigated. Calculi, if present, are removed. A "de Pezzer" catheter is introduced, the mushroom end being just within the bladder, and the incision is sutured with catgut commencing below. The suture is at first through and through, but on reaching the catheter it is reversed and carried back to the lower end as an infolding suture through the muscle coat

only. It is tied at the point of commencement. The abdominal wall is then closed in the usual way.

Drainage is maintained by simple syphonage. If done for acute retention the bladder is not completely emptied, the catheter being clamped, and released at intervals for gradual evacuation. The bladder receives daily irrigation by alternate injection and aspiration of either boric lotion or 1 in 10,000 silver nitrate.

Prostatectomy.

The right forefinger is introduced through the internal sphincter to dilate it, and the mucosa of the prostatic urethra "cracked" immediately below. This is done along the line of least resistance, usually on the anterior or lateral wall, and the line of cleavage is found. The enucleation is then completed in the usual manner, assisted by a finger of the left hand in the rectum.

Great importance is to be attached to the proper control of hæmorrhage. Bleeding is usually very free.

The method used for the control of hæmorrhage in the clinic was the hæmostatic bag of Hagner or Pilcher. As soon as all the adenomatous tissue has been enucleated a special sound (Hagner's) with an olive tip, or any well-curved sound, is introduced through the urethra and the tip made to appear in the incision. The tube connected with the bag is affixed to the olive tip, and the sound withdrawn carrying the bag with it, but leaving in the case of the Hagner bag a cord, and with the Pilcher bag the suprapubic tube, for the purpose of subsequent removal. Traction is made on the tube and the bag drawn down into the prostatic cavity carrying with it the mucosa and any lacerated tissue, thus preventing scar contracture at the internal sphincter and promoting the subsequent epithelialisation of the cavity. Air is then injected with a bladder syringe and the bag distended sufficiently to compress the cavity. The tube is then clamped and subsequently tied, the assistant maintaining steady traction on it throughout the operation. The bladder is inspected and all clot and debris removed. A large rubber drainage-tube is inserted and fixed in position with a stitch, the end being left long so that a tube can be connected for syphonage. This completes the two-stage operation, while the one-stage operation is completed in the way described under suprapubic cystostomy.

Dressings are applied and the end of the tube held by the assistant is attached to a cage, invented by Cabot, which maintains traction but still allows the patient to move. It consists of a tripod with a V-shaped rubber-covered base which is applied to the perineum. A large pad of cotton-wool is placed within the frame to support the scrotum. Tension is released from the bag and the cage removed after 18 to 24 hours, though this may be done after 8 to 10 hours if much discomfort is caused. Should bleeding recur the cage can easily be replaced. About 24 hours after operation the air is released and the bag given an hour to collapse and then removed in the following manner: The drainage-tube is first withdrawn, and the portion of the urethral tube projecting beyond the meatus is cleaned with spirit lotion and then lubricated with K.-Y. antiseptic jelly. Gentle traction on the supra-pubic cord or tube will readily remove the bag. A de Pezzer catheter is introduced into the bladder and any small clots removed by the injection and aspiration of boric lotion with a syringe. This also shows that the catheter is properly placed in the bladder for syphonage, which is then instituted, and should keep the patient quite dry. The scrotum is supported by a suitable suspensory bandage, as it appears that support tends to minimise the chances of epididymitis. This complication was rare in the clinic, and bilateral vasectomy was not considered necessary.

The subsequent care of the patient is as follows: Daily injection and aspiration of the bladder with boric lotion, and the urethral injection of 15 c.c. of a 1 per cent. solution of mercurochrome. This procedure aims at introducing an antiseptic into the prostatic space where infection is most likely to commence. All patients are put on extra fluids, and on 30 gr. of hexamethylene

a day from the time of admission. The de Pezzer is replaced by a smaller catheter after four or five days, and at the end of eight to ten days a temporary clamp is applied to it for a short time and the patient instructed as the bladder fills to try to void per urethram. This is repeated twice and for longer periods on the next day and the patient usually succeeds in passing a small quantity of urine. The following day the catheter can be removed, and the patient instructed to void hourly, the suprapubic dressing being changed as required. In 24 to 48 hours the patient should be dry. If difficulty is experienced the probable cause is that the bladder has been markedly atonic and has not yet recovered its muscle tone. In this case a catheter (soft rubber) should be passed and tied in, and the wound will close rapidly.

The technique described has been practised by Prof. Cabot for many years, and the clinic mortality is under 4 per cent., although the majority of the operating is done by his assistants.

Fashions and Fads in Medicine.

British Med. Jl., May 30, 1925, p. 995.

IN an address on "Fashions and Fads in Medicine" Dr. Robert Hutchison deals with an interesting psychological problem. He quotes Dr. Harris who wrote as long ago as the middle of the eighteenth century—"For some different modes and customs, sometimes perhaps better, sometimes worse, come into fashion and go out again in physics as well as dress; and the common herd of physicians too easily give credit to the promises of new leaders, till that faithful mistress experience at last shows them safer ways to Truth."

The faddist who is to succeed in making his fad a fashion must not only be a person of prominence; he must also be instant, both in season and especially out of season, in preaching his doctrine—as, indeed, most faddists by nature are. Reiteration is essential; he must proceed on the principle that "What I say three times is true," and he will infallibly obtain many disciples.

The late Dr. Mercier, said "the faddist is constitutionally incapable of weighing evidence, of suspending his judgment, or of entertaining doubts," and, as Macaulay said, he is "utterly lacking in the faculty by which a demonstrated truth is distinguished from a plausible supposition."

The man whose attention is confined to one disease is very apt to become faddy about it and to see it everywhere. His mind becomes subdued to what it works in. Tuberculosis officers, for example, are prone to find every lung "suspicious," whilst workers in V.D. clinics soon come to see everything through what Dr. Gee called "a syphilitic fog."

Faddery may be achieved through lapse of years, as a form of senility, and may be due to a thickening of the cerebral arteries. Fads are also acquired through a restless desire for novelty. A doctor may become faddy through trying to be too clever; the pseudo-scientific crank is the most dangerous of all. An ordinary "unscientific" practitioner, for instance, would never have entertained such ideas as these (quoted from a letter in a medical journal).

"Why not attribute neurasthenia to variation in the constitution of the blood, perhaps of its mineral constituents (for example, calcium) or its endocrine factors (for example, hyperthyroidism), or its vitamins, or some of its other components; or very frequently, to the presence of some toxin? Such a conception would give us the explanation of the wide distribution of the complaints in neurasthenia, and would offer a hopeful prospect of research. . . . In practice, when dealing with neurasthenia, I first suspect hidden dental sepsis, then insufficient diet (vitamins, etc.), often prescribe lime and cod-liver oil, as well as milk, egg, butter, green vegetables, fruits, and even try a polyglandular endocrine capsule in accordance with its indications."

Finally, some have faddery thrust upon them by their

teachers. Those who have the duty of training the rising generation of doctors have a great responsibility in this respect. It is easily possible for teaching to be too "up to date." It is always well, before handing the cup of knowledge to the young, to wait until the froth has settled.

Another potent generator of fashions in medicine is the advertising activity of the modern manufacturing chemist. We all know those pieces of blotting-paper which week by week drop from the skies on our desks and try to persuade us—and often succeed in doing so by a process of summation of stimuli—to prescribe for our patients a particular drug or food. The chemist goes outside his proper sphere when he tries to form fashions in pathological belief by issuing booklets or even magazines devoted to such subjects as uric acid, auto-intoxication, and endocrines and the part they play in the production of disease.

Certain factors combine to maintain the momentum of a fashion for a time. Chief amongst these must be reckoned the herd instinct. "All we like sheep have gone astray." The desire to be in the swim, not to be "out of the movement," or to be "up to date," makes many a worthy man fall in with the fashion of the moment. Further, once a treatment has become fashionable the public demand for it helps to keep it alive. There is no doubt, for example, that the public, or at least the more educated part of it, often demands from the doctor such methods of treatment as vaccines or psycho-analysis, or whatever may be the *dernier cri*, whether his better judgment approves them or no. As an anonymous writer has said:

It is easier for fat old sinners to paddle about barefoot in the dew at a Kneipp cure than to abandon at once and for ever their little darling sins of greed or indolence. There can be no doubt that every fashion does effect some cures. It does so, we know, through the power of faith and suggestion, which is the meaning of Trousseau's well known advice to a patient, "Take this while it is still curing." But by and by, when the novelty has worn off, the cures cease.

There are a few members of our profession who exploit fashions and play up to the public demand for them because it pays so to do. Many pioneers in medicine—Jenner, Semmelweis, and Lister,—have been denounced by their contemporaries as cranks. It may be said that there is, after all, "something in" most fashions, and that by summarily repudiating them we run the risk of throwing the baby away with the bath.

There is truth in this, but on the other side of the account is to be reckoned the harm fashions do in lowering us in public esteem of which I spoke at the outset of this address. It is bad enough, in all conscience, that the saying "doctors differ" should have become a proverb. But it is worse still that we should exhibit such a collective variability in our views and practice from year to year; that we should at one time attribute most human ills to uric acid, at another to auto-intoxication, to oral sepsis, to "disturbance of the endocrine balance," or to avitaminosis; that our pathological beliefs should be dominated now by "toxins," now by "reflex action," or by "vicious circles"; that to-day we should seek to cure all manner of disease by excising the ovaries, to-morrow by removing the appendix or the teeth; one year by the injection of sea-water, another by the administration of sour milk, or by the application of violet rays; that we should pin our faith for collective salvation sometimes to "team work," and at others to "early diagnosis" or "preventive medicine"; in short, that we should be as much at the mercy of the "stunts" as the yellow press, as much the slaves of catch-words as politicians, and as intellectually unstable as a popular electorate.

Fortunately many have a natural immunity to fashions and fads. They are individualists, lacking in the herd instinct; sceptical rather than dogmatic; pessimists rather than optimists, with a sense of humour and a natural instinct for truth.

The anti-fad temperament has its own drawbacks. It is possible, "to carry common sense to the point of a vice." The acquired scepticism of age also is not without danger. As Mark Rutherford warns us in *Deliverance*:

"A man must for ever keep himself open to the reception of new light. As he gets older, he will find that the tendency grows to admit nothing into his mind which does not corroborate something he has already believed, and that the new truth acquired is very limited. If he wishes to keep himself young he must use his utmost efforts to maintain his susceptibility."

On the other hand, it is possible to have too open a mind. There are some propositions ("E.R.A." for example) of which one should be able to say, "This is certainly not true, or, if it is, it has no right to be." On the whole, perhaps, we cannot do better than follow the advice of Pope:

"Be not the first by whom the new is tried,
Nor yet the last to lay the old aside."

The so-called *intelligentsia* are the most gullible of all. It would almost seem, indeed, as if everyone has a certain stock of credulity, and the more sceptical he is in everything else the more credulous is he in matters medical.

Mathews Duncan said that "there are more quacks inside the profession than outside it." If education is to help us it must be a more humanistic education.

Sanity, humour, breadth of view, and a power of criticism are, it has been said, the marks of humanism, and the result of a humanistic education is a critical, humorous spirit with a sense of proportion, not given to extremes and with some sense of historical perspective and some logical faculty.

We want, in short, more of the Hellenistic spirit, the spirit of common sense, sanity, and moderation. To quote Professor Gilbert Murray:

"If you look at a Greek statue or bas-relief, or if you read an average piece of Aristotle, you will very likely at first feel bored. Why? Because it is all so normal and truthful; so singularly free from exaggeration, paradox, violent emphasis; so destitute of those fascinating by-forms of insanity which appeal to some similar faint element of insanity in ourselves. . . . What is at the back of this sort of feeling? It is the same psychological cause that brings about the changes of fashion in art and dress; which loves 'stunts' and makes the fortunes of yellow newspapers. It is boredom or ennui. . . ."

It was this spirit of sanity which informed Greek medicine, so that, as Dr. Singer says of the physicians of the Hippocratic school:—

"They remain for the most part, patient observers of fact, sceptical of the marvellous and the unverifiable, hesitating to theorize beyond the data, yet eager always to generalize from actual experience; calm, faithful, effective servants of the sick."

Apart from such an education as this, a sense of humour is the best defence against fads and fashions, and ridicule is the weapon most adapted to their destruction. It has been remarked that there is no use in arguing with a prophet; you can only refuse to believe him. And so there is no use in arguing about a fad or a fashion; you can only laugh at it. If someone tells you, for example, that he is able to cure most diseases, from a common cold to cancer by putting his patients on the diet of King Nebuchadnezzar, you can only smile.

We tend to deal too tenderly with the crank who is allowed too much rope in our medical societies, journals, and newspapers.

He should be less the slave of the advertising chemist, less afraid to use his own judgment and common sense, and should not allow himself to be bluffed by faddists, however eminent. For, after all, the test of truth is in its practical results, and it is by the experience of the general practitioner that in the last resort all fads and fashions must be judged. Perhaps in the final analysis, however, the conclusion of the whole matter may be that both faddists and anti-faddists are required for

progress; that we must always zigzag towards our goal like a ship tacking against the wind—now going too far to the right, now to the left; that, in a word, both the "crank" and the brake are necessary for the machine.

Finally, there are fashions in doctors. It is difficult to explain what makes for success in our profession. It certainly does not seem to be a question of knowledge, nor yet of manners, nor even of character or morals.

Why does such a song as (let us say) "Yes, we have no bananas" sweep a continent, when a hundred others with equally foolish words and no less catchy an air drop still-born from the lips of the music-hall comedian? "Sir," said Dr. Johnson, "it is in vain to try to explain the inscrutable."

In some cases, of course, a doctor becomes the fashion by skilful self-advertisement, "by toying," as Sir William Osler said, "with the Delilah of the press, but many a man has become the fashion *malgré lui*, and it would be a profound mistake to suppose that all fashionable practitioners are charlatans. On the contrary, many of them have been and are men of whom any profession might be proud; for example, Asclepiades in Roman times and Tronchin in eighteenth century France."

One should not envy the fashionable doctor; rather should one wonder at him. He leads a life of slavery, even although, as a wag said, it is slavery on the guinea coast; and, circumstanced as he is, good and thorough work becomes impossible. His position, too, is always precarious. He has, it is true, his little day, but he is apt to wake up one morning to find that his worshippers have stampeded *en masse* overnight to some newer shrine of the fickle goddess Fashion.

Wounds and other Injuries in their Medico-Legal Aspect.

By SIR BERNARD SPILSBURY, M.B., B.Ch. (Oxf.).

Lancet, April 11, 1925.

Fractures of the cranial bones are distinguished from other fractures by the difficulty in many cases of estimating the degree of force that caused them, and of determining its point of application and direction. This difficulty is the result of the complex physical problem presented by the skull with its contents, and by the inadequate information in many cases as to its circumstances in which the injury was inflicted. If, for example, the victim was knocked down by a moving vehicle there may be no information as to where the vehicle hit him, as to what part of his body struck the ground, and as to whether he was dragged or crushed by the vehicle as he lay upon the ground.

Scalp injuries often give valuable information as to the point of application of the force, the nature and shape of the striking surface, and sometimes of the direction in which a blow was delivered.

Drunkenness predisposes to head injury on account of the general muscular relaxation, so that in falling the head strikes the ground with greater violence.

Pathological changes in the skull may greatly affect the formation and extension of fractures. Extreme thinness of the whole of the vertex of the skull is occasionally found at any age; the condition may be due to slight internal hydrocephalus or other pathological condition, producing increased intracranial pressure of long duration; no cause for the condition may be found. There are examples of fracture produced in very thin skulls by slight causes.

Obscure conditions of local or general thickening of the skull will have the opposite effect.

Fractures of the skull are produced by the application of force directly to the vertex or base, but the base suffers far less frequently from direct violence. The anterior fossæ are occasionally fractured by blows reaching the roof of the orbit, or nose, the middle fossa through force acting through the mouth or pharynx, and the posterior fossa may be injured by force transmitted upwards by the spine, or through the upper part of the back of the neck.

Far more frequently fractures in the base are the result of the extension of fractures produced by violence applied to the vertex, the fracture starting at the point of impact on the skull, and running downwards in a line which is fairly straight, when allowance is made for difference of strength and irregularity of shape of the base; this line corresponds with, or is parallel to, the direction of the force.

Fissured fractures often cross foramina; in one case a fracture which started at the occipital protuberance, as the result of a fall on the back of the head, ran downwards and forwards in the middle line to the foramen magnum; it continued its course in the middle line for another inch from the anterior margin of the foramen. Occasionally a fissured fracture starting near the junction of vertex and base will run through the vertex rather than downwards.

When very considerable force is applied over a small area of the vertex, a local fracture may be produced, which corresponds in form with the striking surface. Thus, the fracture produced by a penetrating stab with a sharp knife, or by the edge of a heavy sword, may exactly fit the part of the weapon which penetrated the bone. If the weapon has a thick blade and a wedge-shaped edge, as for example a hatchet, a fissured fracture may extend for some distance from each end of the cut produced by the blade.

A very severe blow with a blunt weapon, such as the head of a hammer, may produce a local depressed fracture corresponding accurately, on the outer surface of the skull, with the striking surface of the weapon. But, as in the case of bullet injuries in the skull described in the first lecture, the extent of the fracturing of the inner table is always greater, and generally of more irregular shape. Occasionally the outer table will scarcely be indented whilst the inner table is markedly depressed. Very rarely the outer table is driven inwards, and the diploë crushed, without apparent damage to the inner table.

It may happen that a depressed fracture of unusual shape will enable the weapon to be identified.

The fracture produced by a stick, or a poker, when great violence has been employed is an elongated, gutter-shaped fracture. The depressed fractures produced by weapons having a limited striking area, and many of the fissured fractures produced by these weapons, are compound, the soft tissues covering the bone being split open in the area of greatest compression. Fissured fractures of the base, laying open the sphenoidal or other sinuses, are also compound, and death may follow from meningitis.

The squamous portions of the temporal bones are generally thinner than the rest of the vertex; the diploë may be absent, and the two tables united to form a thin plate of compact bone; a similar structure is sometimes present in the posterior fossæ below the level of the lateral sinuses. Less violence is necessary to produce fractures in these areas.

When the skull is extremely thin all over, the jarring due to a slight blow or fall may produce a fracture in an area at a distance from the point of application of the force, which does not coincide in direction with the force, and which is not in the contre-coup position. The groove for the middle meningeal artery and its branches may be unusually deep and its floor may consist of very thin bone; a fracture may arise in one of these grooves and may extend along it and its branches without involving any other part of the skull. The middle meningeal artery is likely to be torn, and an extradural hæmorrhage produced as a result of such an injury.

Contre-coup injury to the brain varies in degree. Sometimes the damage is confined to a few small vessels in the pia mater; in other cases there is superficial bruising of the brain, and in more severe injuries the bruising extends deeply, and may be followed by considerable hæmorrhage into the substance of the brain. Occasionally contre-coup injury to the brain is produced by its projection against one of the fibrous

septa of the dura mater, especially the falx cerebri, the injury being found on the mesial aspect of the cerebral hemisphere on the side on which the blow has been delivered.

It occasionally happens that a person receiving a blow upon the head dies from extradural hæmorrhage due to rupture of the middle meningeal artery, without fracture of the skull, which in these cases is generally abnormally thin; the hæmorrhage is probably due to laceration of a branch of the artery, produced by sudden deformation of the skull.

Occasionally, also, a fall produces injury of the brain, sometimes in the contre-coup position, terminating fatally, without producing a fracture of the skull.

In infants injury to the brain is found only in the more severe cases, and then usually along the line of the fracture; contre-coup injuries are not found, the earliest age at which Sir Bernard saw them being at 2 years and 8 months, in a boy who was being carried across the road by a brother, when they were knocked down, but not run over, by a motor-car.

The intracranial effects and complications of fractures may appear either immediately or after a variable interval of time; occasionally they only become manifest a long time after the injury has been inflicted.

Death may be due to concussion, no gross change being found in the brain, except a little blood in the cerebro-spinal fluid of the lateral ventricles.

Injury to the arteries within the skull may give rise to remote effects. An artery may be crushed and injured by sudden pressure of the brain against the skull, or may be stretched and torn by a violent blow upon the head. The injury, if it does not result in immediate rupture of the artery, may be followed by the development of an aneurysm.

A young man, aged 22, who was said to be perfectly healthy, slipped and fell in the street, and lost consciousness for about five minutes. He recovered and went home, where he said he had ricked his head. He was never well after the accident, complaining of pain in the head; he had frequent vomiting attacks and suffered from sleeplessness; his vision also became impaired. Fourteen days after the accident he had what appeared to be a fainting attack; four days later he became unconscious immediately after he went to bed, and died three hours afterwards, having had attacks of vomiting and frequent fits during that time. On post-mortem examination he was a well-nourished, muscular man. There were no external injuries. On opening the head a saccular aneurysm was found on the left anterior cerebral artery, close to its origin; the aneurysm had ruptured into the left frontal lobe and had burst into the lateral ventricle, all the ventricles of the brain being filled with blood. There was a little meningeal hæmorrhage between the frontal lobes, and more around the pons and cerebellum. There was no brain disease; the cerebral arteries were otherwise healthy, and no disease was found in the body. There were no indications of syphilitic or tuberculous disease on microscopic examination of the wall of the aneurysm.

The Medical Witness.

By H. H. JOY, K.C.

British Med. Jl., June 27, 1925, p. 1159.

In this paper Mr. Joy gives valuable advice to medical men who are called on to give evidence in the Courts of Law. Immense responsibility attaches to the medical witness, he is almost in the position of a man who is interpreting for the court from some foreign language, and accordingly it is obviously his paramount duty to be scrupulously fair. Medical witnesses as a class prove worthy of the high confidence reposed in them. Speaking generally the ordinary witness may only give evidence as to facts, and from these facts the court draws its own conclusions; but the medical witness is permitted to give his opinion upon

the facts which he has observed, or which are submitted to him.

If the nature of the case to which a doctor is called is such as to suggest to him the possibility of ultimately being required to give evidence he should observe and record most fully everything that he finds. When he is asked to examine a patient with a view to being called as a witness, he may probably be furnished with views or theories by the party engaging his services. He should keep an open mind; he should make his examination fully first and then see to what conclusion it leads; if he cannot to his own satisfaction support the case let him say so plainly if he can, let him be careful to include in his "case notes" everything which really affects his conclusion. It may be a long time before he finds himself in the witness-box and when there he may refresh his memory from his notes; but he may also be asked to show them to the counsel for the other side; obviously if something to which his evidence he has attached importance is not to be found in the note made at the time he lays himself open to criticism.

But the doctor should not make a habit of using these "notes" too liberally—any "refreshing" should be done before entering the witness-box; a witness is not likely to create such a good impression on the court if he gives the appearance of not knowing the facts.

If in the progress of the case facts new to you come out which cause you to modify or even alter your views you will naturally have to act accordingly if you go into the witness-box; but in such a case take care to let counsel know how the new or altered facts affect your view.

The simpler the language of the expert the greater is his effect upon the court. In a case before a judge and jury a doctor stated in his evidence that "on examining the prosecutor he found him suffering from a severe contusion of the integuments under the left orbit, with great extravasation of blood and ecchymosis in the surrounding cellular tissue, which was in a tumefied state; there was also considerable abrasion of the cuticle." The judge: "I suppose you mean that he had a black eye?" The doctor: "Yes." The judge: "Then why not say so?"

When you are being cross-examined keep your temper, for the gentle art of cross-examination embraces infinite styles and varieties, and some must be enough to try the temper of a saint. Listen carefully to the question; beware of double questions, and if you do not understand what is put to you, say so and get it made intelligible to you before you answer. When being cross-examined do not merely answer Yes or No to medical questions; such questions are put to you presumably—at least they should be—because the witnesses for the other side are going to give them as their views, so explain your reason for not accepting what was put to you. Avoid arguing with the cross-examiner; if there is anything you consider really objectionable in a question or in the way of putting it appeal to the judge—you are entitled to be protected from unfair treatment—but, of course, don't do that unless it is really bad. If an extract from a book is cited to you in cross-examination, remember that you are fully entitled to see the passage and its context before you give your answer; it not infrequently happens that when investigated with its context the point which was intended to be made against you wholly collapses; or the quotation may be from a standard work now out of date; or from an old edition of a work, in the recent edition of which a different view is given; or it may happen (indeed, has) that the passage was one cited by the writer of the book for the purpose of contradicting it or exposing its fallacy. But when you know that you are giving a view which is really contrary to the usually accepted view, be ready to fortify it by your special experience or other good ground.

If, in cross-examination you find yourself being cross-examined on a subject on which you have no particular knowledge, do not try to answer; say you cannot

deal with that. The court will esteem you the more highly for not pretending to have knowledge that you do not possess. Avoid making any sort of attack upon the other medical witnesses or giving the impression that you consider yourself far superior.

It is often a matter of amazement to find how completely doctors differ, or appear to differ, from each other in the evidence that they give about a case. Perhaps the most influential reason is that of unconscious partisanship. The ideal medical witness should be on guard against this from the beginning.

In the witness-box, being cross-examined, he feels that it is "up to" him to justify the confidence placed in him by his side; it is human nature to want to "play up" accordingly and almost unconsciously he adds a little or omits a little.

Sometimes the cause for this difference of views is of quite another kind; there may be a real division in the profession upon the point under discussion—some think this, some that. Here is a chance for you to help counsel.

If you make a deduction from certain stated facts, be quite sure there is no flaw in your deduction. No less a person than a very learned judge whose face was an exact counterpart of that of George III on the coins, on one occasion when counsel was inviting a jury to infer a certain consequence from the likeness of two people to each other, interrupted him saying, "Don't dwell too long on that. It has been said I am the son of His late Majesty George III because of my likeness to him; all I can say upon that subject is this: George III was never in Scotland, and my mother was never out of it; so if you can make me out to be his son, do. Now go on." Counsel, in a stage whisper for the jury to hear, to his neighbour: "But they might have met at the border!"

When you are being cross-examined be on the lookout for questions which assume that you have said something which you have not said, or that something has been proved which has not been proved, and for questions to which you cannot properly answer Yes or No—for example, "Have you given up beating your wife?" Considerable latitude is allowed to the cross-examiner, but he has no right to put unfair questions or make inaccurate statements, and the witness is fully entitled to point out the inaccuracy, and, in extreme cases—to appeal to the judge if he thinks the question unfair. When you feel that you have scored a point and floored the cross-examiner with your answer, be content—do not try to kick him as well.

Your function is to assist the court to arrive at what you believe to be a correct conclusion upon the medical question in the case, and you will do that most effectively by not showing any resentment at cross-examination, or trying to score off counsel personally, but by answering the questions courteously and simply; and, as opportunity arises, giving the reason why you cannot accept this or that suggestion that is put to you.

For a witness in court there is no privilege recognised by the law as regards facts which the doctor may have observed or with which he has become acquainted in his capacity as medical attendant.

In many cases it must be very unpleasant for a doctor to find himself asked to disclose information about his patients; but he can do no more than appeal to the judge to know whether he is bound to answer. The judge will say Yes; but the doctor will feel that he has done what he can to preserve the confidential relationship between himself and his patient. If he persisted in refusing to answer he would be liable to be committed for contempt of court. Incidentally, what a witness says in the witness-box is privileged, which means that it cannot be made the subject of an action for slander.

Stovarsol.

In the treatment of amœbiasis, emetine still to-day holds the first and most honoured place. On the other hand—as Dr. Manson-Bahr has noted in a recent review

of the literature—it is becoming increasingly evident that, whilst emetine is the most rapid line of clinical cure for amebiasis, it is doubtful whether any infection of a patient with *Entamoeba histolytica* in the colon can be absolutely eradicated by emetine therapy; far more often what happens is that the patient is clinically cured, but the parasites are still there, and relapses are all too likely. In other words, whilst emetine therapy is the first line of treatment, other lines of treatment should be investigated—either to replace or to supplement emetine therapy.

In such supplementary or primary therapy, arsenic is a drug of considerable importance, both from its protozoocidal and tonic actions; and in recent literature "Stovarsol," a purified organic product prepared by Messrs. May & Baker, London, has received much attention. In a recent article in the *Paris Medical*, Dr. E. Marchoux, of l'Institut Pasteur, Paris, speaks of the drug in very high terms. He quotes cases of amebic dysentery, one treated by Delancé and apparently cured; a very severe case cured by de Chauliac; three cases, two of which were cured, but one relapsed, treated by Legar and Nogue in the Senegal; Fontanel as having cured three obstinate cases of long standing; Rubenthaler and Jausion as having cured five cases; and other authors as claiming that not only is the amebiasis clinically cured, but that subsequent examinations of the stools have failed to shew the specific parasite.

Marchoux's series now reported consisted of 59 persons suffering from infection with *E. histolytica*, treated between March 1923 and July 1924. Of these 59 cases, 3 had acute amebic dysentery at the time, the others were carriers, in many instances with a history of previous or chronic amebic dysentery, and of relapsing dysentery. All were treated with "Stovarsol," given orally, for six weeks.

Subsidiary measures consisted merely in forbidding smoking and alcohol, and in the avoidance of butter—which is stated by Pavlov to inhibit gastric digestion. For patients with achlorhydria, a mixture of hydrochloric and phosphoric acids was prescribed. The dose of "Stovarsol" given in the majority of cases was one of the 4-grain tablets, taken with food, twice a day, representing a total of about 0.5 gm. per day; in some of the more intractable cases as much as 1 gm. was given per day.

In 2 of the cases "Stovarsol" was unsuccessful; in the first no improvement occurred on small doses, the patient left Paris and further observation was impossible; in the second the condition at first improved rapidly, but a relapse occurred each time the treatment was stopped, and the patient also left Paris. In addition to the cases of amebiasis, 21 patients infected with *Giardia (Lamblia) intestinalis* were treated with Stovarsol.

In general, Dr. Marchoux reports that under this treatment the condition of the patients improves rapidly, their discomfort disappears, their diarrhoea or dysentery abates, their general condition improves; "cysts diminish in number and disappear; soon afterwards the most rigid investigation fails to reveal a single one." Above all the mental and psychic condition of the patient improves to a remarkable degree. He sums up his conclusions in the following terms:—

- (1) Stovarsol cures amebic dysentery.
- (2) It destroys *Blastocystis hominis*—(an organism which he clearly regards as pathogenic).
- (3) It cures certain cases of lambliaosis, and benefits all.
- (4) It stops indigestion, because the arsenic in this form promotes the action of the digestive diastases and prevents putrefaction of the undigested waste products.
- (5) It cures diarrhoea, toxic neuralgias (such as lumbago, sciatica, intercostal neuralgia, etc.), and lessens the severity of expulsive gingivitis.

(It will be seen that the claims made for "Stovarsol" are of a very high order. The literature is at present being so flooded with reports on new remedies for amebic dysentery, however, that a most critical atti-

tude is necessary. At the Calcutta School of Tropical Medicine, "Stovarsol" has been on clinical trial for a year, and it is hoped shortly to collect the results for publication. It may immediately be stated that, as Professor Marchoux has found—in common with other workers—many cases of amebic dysentery and of tropical diarrhoea clear up at once on Stovarsol treatment, and improve enormously in general condition and mental outlook. Secondly, the treatment is one very easily administered, it avoids the painful experience of emetine injections. Thirdly, however, caution is necessary and the avoidance of too prolonged courses of treatment, owing to the possibility of ocular trouble. Finally, with regard to the question as to whether systematic treatment with Stovarsol will eradicate the infection with *E. histolytica* and cure the carrier state, it is as yet too early to make any definite statement; a large number of patients should be kept under prolonged observation after treatment, and their stools frequently and systematically examined. In our opinion, in brief, Professor Marchoux's statement is almost too optimistic. "A good wine needs no bush," but the question of the eradication of an infection with *E. histolytica* is one which demands prolonged and most careful study. That patients do recover from the carrier state and that infection with *E. histolytica* can be not merely clinically cured, but absolutely eradicated, is certain; the final cure probably rests, not with any drug, but with the patient's powers of resistance; that arsenic may be of considerable value in raising this resistance is very probable. Clinically, however, Stovarsol is a drug which may be recommended with considerable confidence to the medical profession.)

Reviews.

AN INDEX OF TREATMENT.—By various writers. Edited by R. Hutchison, M.D., F.R.C.P., and J. Sherrin, C.B.E., F.R.C.S. 9th Edition. Bristol: John Wright & Sons, Ltd., 1925. Pp. 1035. Price, 42s. net.

THIS well-known book has gone through nine editions, two of which were reprinted, in 18 years. The last edition was published in November 1921. A number of the articles have been rewritten entirely and all of them have been revised; a few, those dealing with infective endocarditis, spinal analgesia and surgical tuberculosis have been added. Most important alterations have been made in the articles on certain subjects, for example in the articles on asthma, diabetes, syphilis and certain tropical diseases.

The contributors number nearly a hundred; each has written on the subject or subjects on which his opinion is authoritative. The list includes the names of practically all the leading physicians and those of many of the best known surgeons. The tropical diseases are dealt with by authorities on these subjects.

The physician in the tropics is liable to judge the value of a book on general medical treatment by the way in which the tropical diseases, with which he himself is familiar, are dealt with; his confidence in this book will not be shaken, if he judges it in these lines. All recent advances in the treatment of tropical diseases have been included. In the section on malaria we particularly welcome the opening paragraph "quinine is the only drug that can be said to be a certain cure, but the method of administering the dose, and the compound used, vary in individual cases." This fact cannot be emphasised too much. There would appear to be a huge conspiracy to contradict this statement if one is to judge by the number of "specifics" for the disease, "guaranteed to contain absolutely no quinine," which are put on the market.

The book is nicely balanced throughout. No subject appears to be neglected and on no subject has too much

and jungles, which accounts for the observed fact that the general health of the people is better in time of scarcity, and is not seriously affected until actual famine prevails.

It has been truly observed that the majority of mankind dig their graves with their teeth, and the process may be studied from day to day amongst the general population of any country. The tendency to excessive eating is caused partly by sheer gluttony inasmuch as the satisfaction of appetite gives pleasure, but it is also partly due to an attempt by nature to ensure that a sufficiency of all the necessary component parts of a balanced diet are included.

The absence of balance leads to excess. Excess in eating is only possible when an ample food supply is available but when such is the case, it is the usual practice of the majority. The results are disturbances of digestion and nutrition, which predispose to all sorts of bowel diseases, such as cholera, dysentery and diarrhoea, and which are the direct foundation of many other diseases of metabolism, of which diabetes and cirrhosis of the liver are two only too frequent examples.

A sparse regimen is the golden rule of health, wherefore the poor man has a great advantage in health over his richer neighbour.

The available knowledge as to the scientific balancing of diet is as yet incomplete, but it is at least sufficient to guide us far beyond the present practice in eating.

The accustomed diet, be it based upon rice, or *ata*, or upon meat is, in almost all cases, defective and excessive.

The food is first deprived of its best and most nutritious parts when the rice is husked and polished or the *ata* is ground fine and white, or the potatoes are peeled, and then it is spoiled by cooking which slowly destroys the vital properties, at present known as vitamins, which are essential to good health.

Man is the only animal that cooks his food and he is a fool for his pains. The less food is cooked, the better it is. The longer it is cooked, the more deficient it becomes in vital properties.

The combination of cooking with the removal of the valuable and nutritious skins and inner husks of vegetables, fruits and grain, leads to a deficiency in diet of the vital elements which create and maintain life, and farther leads to excess in eating in the effort to make up for these deficiencies.

Further, the accustomed diets of most races, be they based upon rice, upon *ata* or upon meat are all one sided. The habit is to eat too often of one thing, such as rice, and to eat too much of it and so to clog the body with a quantity of starch which it cannot digest. A balanced diet must contain fresh fruits and vegetables in ample quantity, and should, if possible, include good clean milk, and these things should not be cooked or boiled for more than a few minutes and would be better not cooked at all.

The quantity of any one article of diet of a staple nature such as rice, *ata* or meat should be kept small, and balanced by the addition of fresh fruits, vegetables, and milk, so that the total diet will contain a balanced combination of the essential proteids, carbohydrates, fats, and mineral salts, together with an ample supply of the essential vital elements.

Lop-sided, badly balanced, diets deficient in vital elements are in general use and are the direct cause of many diseases such as beri-beri, epidemic dropsy, scurvy, etc., and are the most potent cause of general ill-health and debility and the most common predisposing cause of all other diseases. Much has been written about immunity and how to create protection against disease and how to cure it by disinfectants, drugs, and inoculations. But the last word in the story of health is this,—that a healthy body is the best defence against disease, and the golden rule of health is to eat little and wisely."

Chief Diseases.—There is a remarkable difference in the distribution of disease in urban and rural areas. The infectious diseases, the spread of which depends upon overcrowding, density of population and the con-

sequent facilities for infection, are consistently more prevalent in the towns: whereas fevers, of which malaria is the chief, are more prevalent in the rural areas, where the facilities for anopheline breeding are greater and where the economic condition of the people is frequently not so good. The large towns are hotbeds of consumption, and this disease, together with pneumonia and influenza, causes the death rate from respiratory diseases to be many times greater in towns than in rural areas. Similarly, cholera and plague are more prevalent in the towns than in the villages.

Cholera.—The provincial death rate from cholera rose from 0.2 in 1923 to 2.2 in 1924. The districts of Champaran and Gaya recorded the highest rural cholera death rates, and Katihar, Darbhanga and Revelganj amongst the towns. Special preventive measures were taken, and a special staff employed, as usual, in connection with the *Rath Jatra* festival at Puri and at Sonapur fair. The use of chlorinated lime for disinfecting wells has been generally adopted by the local bodies; the epidemic cadre of 10 assistant surgeons was maintained throughout the year, and a special additional staff of 20 epidemic doctors employed for about six months during the epidemic. A special epidemic reserve of 200 vaccinators was also entertained from April to September for cholera and other epidemic duty. To some extent anti-cholera vaccine was used, of which 4,805 doses were issued. In general the epidemic is fought by treatment of patients with kaolin and permanganate, and disinfection with bleaching powder.

Cholera has always been a scourge in Bihar and Orissa. In previous epidemics the total mortality in the province has reached such enormous figures as from 150,000 to 200,000 deaths; in 1924 the epidemic was fought step by step, preventive measures were taken beforehand, weekly epidemic reports were utilised to indicate centres which should be taken in hand before mortality rose, and towards the end of September the epidemic abated. The total cholera mortality for the year was only 77,480; and the figures shew what can be done by vigorous and anticipatory measures.

Small-pox incidence also rose during the year, and it was severe in the towns of Bhagalpur, Chakradhapur and Bettiah. The death rate from fevers rose from 17.6 in 1923 to 19.3 in 1924. Colonel Ross is of opinion that relapsing fever occurs in the province, although its existence has not yet been demonstrated. Malaria, although a cause of vast amount of sickness, he considers is not an important cause of the mortality in the province. Plague was unimportant during the year.

Propaganda work was steadily pushed during the year, and much excellent spade work is being done in this connection. The five school medical officers visited 246 schools during the year, examined 11,392 pupils, and delivered 1,417 lectures. Village sanitation is at present reported to be a negligible quantity; "village unions steadfastly refuse to tax themselves and their revenues are too small to enable them to carry out any serviceable sanitary programme. In the majority of cases a large portion of their revenues is wasted on the payment of a clerk and a peon who have practically no work to do." The results are profoundly discouraging.

The number of food samples found to be adulterated was very high; 48 per cent. of samples of *ghee*, 94 per cent. of *ata* and flour samples, and 47 per cent. of milk samples were found to be adulterated; what this means in the deterioration of public health is best left to the imagination. A Food Adulteration Act exists, but in the hands of municipalities and district boards it is largely a dead letter.

Public Health Policy.—Finally, Colonel Ross has some interesting remarks to make on the necessity for a public health policy in the provinces in India. "The issue is simple," he writes. "Public health is directly concerned with the health of the community and indirectly with its prosperity, contentment and happiness, which are all in part the outcome and in part the accompaniment of good health and working capacity. Public health

includes within its scope both the prevention and the cure of disease, and all the measures that appertain thereto. Curative medicine deals with the individual. Preventive medicine deals with the community, and is a greater application of the principles of medical science to greater numbers. It is, in short, the result of a process of evolution in the application of medical knowledge and is recent in origin, and as yet undeveloped, insufficiently appreciated, and inadequately applied.

In the application of scientific knowledge to the uses and the benefit of the people there are natural subdivisions of activity: in curative medicine, the individual doctor treats the individual patient: in preventive medicine, the individual element is subordinated, a specialised staff is employed by the state or by local bodies to advise the administration, and to supervise the measures adopted with regard to the betterment of the public health: in the determination of policy, the application of legislation, and the carrying out of approved measures, the administration consummates the process. It is by the perfect co-ordination and development of these three activities that public health may come into its kingdom and that lasting good may be done.

In the control of public health it is first essential that there should be a definite policy, and such policy should be founded upon exact scientific knowledge, interpreted and applied to the benefit of the community.

The second essential is careful and complete organisation with the purpose of getting the best and most rapid results at the least cost. In the execution of preventive measures, good organisation is the key to success and such organisation must be created and maintained before any effective work can be done. It is quite useless and very wasteful to undertake *ex-tempore* preventive measures, and create a temporary staff for preventive work when an epidemic is raging and widespread.

The essence of prevention lies in anticipation. Unless the preventive organisation is in being and ready to deal at once with the first outbreak of epidemic disease, it is better to realise the hopelessness and futility of preventive work and to concentrate chiefly on measures of relief.

The struggle between health and disease is a state of war and the preventive organisation is the army which defends the health of the people. In war itself it is an axiom that a people must be prepared always beforehand with a highly trained army. The analogy is perfect. The preventive army must also and always be prepared beforehand, and be ready to engage in the fight without delay. Delay is fatal, and the time factor is all important. It is for this reason that all nations and peoples maintain a fighting army for the protection of the nation, and it is for this reason that a preventive army must be maintained and kept ready to safeguard the health of the people.

The third essential is obviously to provide the necessary funds. No army can be maintained without cost and no army should be maintained unless there is some advantage to the community in doing so. The uses and advantage of a preventive army are obvious. The people can be protected from decimation by the ravages of epidemic diseases and the saving of lives and the prevention of disease build up a stronger and more virile population with greater working and productive capacity, which is better able to live and enjoy life, and which is economically more prosperous. The gain is a double one, both in health and in wealth, and will more than suffice to pay the price of protection from disease.

Existing legislation is defective and inadequate in many ways and new legislation is very necessary if any real progress is to be made. Such legislation as is needed must be more simple, more concise, more comprehensive, and must give a strong and definite lead, with a view to requiring and directing a definite advance in public health standards and administration. The only question at issue is:—How far is it wise to go? It is admittedly useless to legislate too far in advance of public opinion, but on the other hand it is equally certain

that legislation must either go in advance of public opinion and give it a lead—wisely and without undue pressure—or it must and will lag behind, in which case retrogression will take the place of progress, because of the arrest in the advance of public opinion, and the inertia engendered by the failure to use its influence and stimulate its growth.

It is, I believe, essential to tackle the problems of public health more firmly and with a greater grasp, and to put forward a bigger and a braver policy of legislation and control. The principles of public health are essentially the doctrines of socialism. The greatest good of the greatest number is the basis of both.

The principles and practice of public health betterment have not yet been absorbed nor incorporated in the public opinion and public policy of India. The creation of public opinion and a communal conscience in public health matters is as yet lacking but must necessarily precede any real progress in the betterment of public health. At present therefore it rests with Government to direct and to control all measures dealing with public health and the initiative in all such matters must continue to rest with the administration until public opinion has been formed and has gained sufficient strength to direct its own policy."

ANNUAL STATISTICAL RETURN ON VACCINATION IN BIHAR AND ORISSA FOR THE YEAR 1924-25. BY LT.-COL. W. C. ROSS, M.B., Ch.B., D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, BIHAR AND ORISSA. PATNA: SUPDT., GOVT. PRINTING, BIHAR AND ORISSA. PRICE, 9 ANNAS.

The three assistant directors of public health remained in charge of their circles during the year; the inspecting staff consisted of 20 district inspectors and 69 sub-inspectors, and 1,121 licensed and 222 paid vaccinators were employed in the province during the year. The total number of operations performed was 1,044,282—an increase on the previous year; of which 990,571 were primary vaccinations. In general the proportion of protected children in the province is equal to some 346 per mille, although the figure for municipal areas, 433 per mille, is better. These figures, however, comments Colonel Ross, are unsatisfactory, and they shew that far more than half the total primary vaccinations are carried out on children more than one year old. This is due to the opposition of parents to having children vaccinated in early infancy, and he considers that the Vaccination Act should be amended, and the age for compulsory vaccination raised from six months to one year.

Small-pox was prevalent during the year, and mortality from it rose from 3,893 deaths in the previous year to 8,345 deaths in 1924-25. Colonel Ross predicts that this is but a beginning; "there is a serious risk that the disease may rage in epidemic form during the next two years unless strong action is taken to enforce the vaccination of the population." He considers that small-pox cannot be dealt with satisfactorily in the province unless compulsory vaccination is extended to the rural as well as municipal areas and the whole province included; the age for compulsory vaccination should be raised to one year; vaccination should be free; and supervision and inspection should be delegated to district boards and municipalities and their health officers.

The work of the Vaccine Depôt at Namkum was very satisfactory during the year, and large reserves of lymph are in hand. The number of doses issued was 2,657,321, whilst 2,924,131 doses remained in hand at the end of the year. The average net cost per vaccination works out at only 0.37 pies, if receipts to the Depôt be taken into account. The cold storage plant, which had given constant trouble in previous years, was duplicated, and is now in very satisfactory order. The use of adult animals for obtaining lymph has been abandoned, as there is nothing in its favour.

Further work is in hand with a view to rejuvenating and improving the seed vaccine.

The entire cost of the department for the year was Rs. 1,56,973, which works out at approximately 2 annas 6 pies per successful vaccination all over the province.

REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, PUNJAB, FOR THE YEAR 1924.
BY CAPT. D. R. THOMAS, I.M.S., CHEMICAL EXAMINER TO GOVERNMENT, PUNJAB.
LAHORE: SUPDT., GOVT. PRINTING PUNJAB, 1925. PRICE, 8 ANNAS.

DURING the year 1,569 cases comprising 5,133 articles were examined. There were 537 human poisoning cases, including 4 of criminal abortion; 44 of cattle poisoning, 609 stain cases, of which 345 were cases of murder or hurt by violence. Of the fatal human cases 34 appeared to be due to causes other than poisoning, whilst poison was detected in 81 per cent. of the remaining suspected cases. The poisons employed were very varied, but arsenic, opium, dhatura and mercury were those most commonly employed. In the animal poisoning cases, poison was detected in 46 per cent. Two hundred and sixty-one cases, comprising 566 articles, were sent to the Imperial Serologist, Calcutta. During the year 1,117 articles were examined for purity and quality, as against 533 articles in the previous year. These included water samples, soil samples, cocaine, various drugs, and articles in connection with bomb cases. Of 218 samples of cocaine 58 were found to be adulterated with drugs such as antifebrin.

Captain Thomas' report includes a very interesting list of cases of medico-legal interest from which we have abstracted the following:—

A woman died in Amritsar under suspicious circumstances and the body was burning when the police interfered and had the viscera sent for examination. Arsenic was found.

The body of a female infant aged about two weeks was found in a railway carriage at Rawalpindi one night. The body was very emaciated and the infant might have died of starvation. Arsenic was detected in the viscera.

An old man aged about 60 years died at Delhi where he was being treated for dysentery by some Unani medicines. The wife of the deceased was not of a very good character and doubt arose. His viscera on examination contained arsenic.

Two cases were received from Delhi at various times, one of an old man aged 65 years suffering from asthma and another of a male about 40 years with signs of double pneumonia. Opium was found in both cases. No doubt this drug was taken by the deceased without the knowledge that it was contra-indicated in such complaints.

A body of a female aged 20 years was found buried in a field near Karnal. It was in an advanced state of decomposition and no marks of violence could be made out. Opium was found in the viscera.

The body of a male child aged 2½ days, tied in white latha cloth was dug up from a grave in Jhang District. It was buried in soft sandy soil and was well preserved. The analysis of the organs showed mercury and traces of opium.

During the cold weather a young man in good health went to witness a circus in a village in Patiala State. He was seen drinking during the afternoon. His body was found next day about a mile from the village. Alcohol was detected in all the organs. It was a very cold night and he died from exposure. This is a typical example of many cases that have occurred during the year.

A patient in Chunian, Lahore District, was given by mistake a dose of pure carbolic acid instead of his mixture by the attendant. He immediately showed signs of collapse and died in 45 minutes. The mucous membrane of the whole œsophagus and stomach was

white in colour. Carbolic acid was detected in the stomach and the urine.

Most cases of criminal abortion are carried out by mechanical means with the result that sepsis sets in and the woman or girl dies of septicæmia. One case was received from Lyallpur where arsenic was plugged into the vagina of a young female aged 16 years. It was rapidly absorbed and the usual symptoms of acute arsenical poisoning developed and arsenic was detected in the stomach and liver.

BENGAL PUBLIC HEALTH DEPARTMENT.
DR. SUR'S REPORT ON KALA-AZAR WORK IN HOOGHLY DISTRICT FOR THE YEAR 1924.

DURING the year two kala-azar treatment centres were run, one at Hooghly and the other at Singur. These centres were started in June 1923, with the object of making observations and arrangements in regard to the following matters:—

- (i) to find out the actual intensity of kala-azar in the Hooghly district, as many assert that cases detected in survey work never approach the actual figures, but that it is only when a treatment centre is opened that the real figures are found;
- (ii) to find out the best field method of diagnosis, as many treatment centres are being opened now-a-days and it has become necessary to make a rapid diagnosis;
- (iii) to find out whether a treatment centre can check an epidemic and eradicate it from a locality;
- (iv) to make a treatment centre a training ground for medical practitioners; and
- (v) to give relief to the patients.

Seasonal variation.—The table shows that the number of kala-azar cases rose in May, June and July and then fell; whereas the number of malaria cases began to rise in August, reached its highest in November and then commenced to fall.

Sex distribution of Kala-azar cases.—The number of male patients in the centre was higher than that of females both in kala-azar and malaria, but the proportion of males to females in kala-azar was somewhat higher than in malaria.

Age distribution.—This shows that nearly 72 per cent. of the cases are under 20 years.

Kala-azar Index.—The population of the Hooghly thana, including the Hooghly-Chinsura Municipality is 37,043. No part of this thana was more than three miles from the centre. It might therefore be expected that most cases in the thana would attend the centre. Dr. Sur knows for certain that very few, not more than a dozen, were treated by other practitioners. There being 242 cases from the Hooghly thana in 1924 with a history of a month to a year's duration, the case incidence in that particular year cannot be more than 6.5 per mille, if not less, as some cases cropped up in the year before. The population of Magra thana, including the Bansbaria Municipality is 21,981. The number of cases during the year being 156, the kala-azar incidence of the area is not more than 7.1 per mille, which nearly approximates to that of Hooghly.

I stated in my previous report that in the Chanditala thana of the Hooghly district, the case incidence was calculated after survey to be about 6 per mille.

Diagnosis of Kala-azar.—The diagnosis of kala-azar may be made by—

- (i) finding the Leishman Donovan body—
 - (a) from the spleen and liver;
 - (b) from the peripheral blood, either by staining a film or by culture.
- (ii) serum reaction—aldehyde test.
- (iii) quinine elimination.
- (iv) taking a careful clinical history.

(i) The first method is considered impracticable under the circumstances.

(ii) Aldehyde test:—In the Hooghly kala-azar centre chronic malaria cases also come for treatment suspecting themselves to be suffering from kala-azar.

Altogether 673 aldehyde tests were done. The reaction was put under definite categories, either positive or negative, with no alternative between the two. The positive category included those which turned white with jellification within 24 hours, whilst the negative category included those with jellification but transparency and those with no jellification. All the cases tested were random selections. Of the 673 cases, 305 gave positive reactions and 368 negative reactions. But by clinical history and by adopting a course of treatment it was subsequently found that of these 305 positive reactions 270 proved to be kala-azar. This means that 90 per cent. of the cases positive by the aldehyde test are kala-azar and 10 per cent. are non-kala-azar. Of the 368 negative cases, 154 turned out to be kala-azar.

The non-kala-azar aldehyde positive cases were cured by quinine and remained so for at least six months. In three of them in which the aldehyde test was positive within 5 minutes spleen punctures were performed for corroboration. No Leishman-Donovan bodies were found in the film after long search. The aldehyde reaction, therefore, though useful adjuvant in diagnosis, is not infallible.

(iii) and (iv) Elimination by quinine and clinical history are therefore of more value in diagnosis in a rural centre. In the Hooghly centre, the authors administer quinine in 15 gr. doses daily for a week with two intravenous injections of 10 grs. of bihydrochloride during that period. In 95 per cent. of the malaria cases one injection of 10 grs. with 45 grs. of quinine by mouth for three days and in the remaining five per cent. two bi-weekly (? twice weekly) injections with 90 grs. in a week were found sufficient to stop the fever.

Treatment.—Treatment was carried on with sodium antimony tartarate in two per cent. solution. Additional treatment was also given to improve the condition of the blood.

On the average, five injections were necessary to stop the fever and 21 injections to cure the patient. Not more than one per cent. of the total cases were known to have relapsed within 6 months. Altogether, 19,313 antimony injections were given in the centre. The average daily attendance on injection days during the year was about 150.

Treatment as a method of prevention.—The names of the villages with the number of cases against them that came under treatment month by month in 1924 have been tabulated. The object was to find out whether kala-azar could ultimately be eradicated from a village. For instance, from Rajhat village of Polba thana, 9 cases were admitted in September 1923, 2 cases in October, nil in November, 1 in December 1923, 2 in January, 2 in February, 4 in March, 2 in April, nil in May, 3 in June, 1 in July, 1 in August, 1 in September, 8 in October, 4 in November and nil in December, 1924. Similar examples of other villages might be mentioned. Hence it is apparent that the mere opening of a treatment centre is not all that can be desired for the prevention.

[Comment.—Dr. Sur begins his report by summarising the object of the survey, but does not finish by summarising his conclusions. One, however, concludes that he is of the opinion that a survey will give an accurate idea of the number of cases of kala-azar that exists in any area, and that nothing can be gained in this direction by opening a treatment centre. The figures that he gives certainly seem to prove this case and one is compelled to admit that his treatment centre does not seem to have attracted a larger number of patients than were previously known to exist in this area. His experience is contrary to that of many others.

A great deal depends on his statement that, "I know for certain that very few, not more than a dozen, were treated by other practitioners." This statement suggests a very intimate knowledge of the movements of 37,043 persons.

Dr. Sur presumably considers quinine elimination and clinical history the most valuable means of making a diagnosis in the field. He may be right, but his arguments are not conclusive. He accepts quinine elimination as the crucial test on which he judges the aldehyde test and finds it far short of perfect. If on the other hand he had accepted the aldehyde test as the last word in the matter he would have found the quinine elimination test defective. He found that 33 of the 303 cases that gave a positive aldehyde reaction were not kala-azar. The evidence for this statement is that these 33 out of the 303 patients were apparently cured by quinine and remained cured for 6 months. He does not say whether he traced each one of these patients or concluded from their non-attendance that they were cured. It is a well-known fact that kala-azar patients occasionally show temporary improvement on quinine and that even without treatment of any kind they recover a degree of health for long periods. In three cases spleen puncture revealed no Leishmania infection but again he does not state on how many cases this operation was performed. A single spleen puncture does not confirm the diagnosis in much more than 90 per cent. of cases of kala-azar so that if he did 30 spleen punctures on cases of kala-azar one would not be surprised at his finding three of them that did not show parasites.

The aldehyde test is a non-specific one. As far as Bengal is concerned it can be claimed that more than 99 per cent. of cases giving a strongly positive aldehyde reaction are cases of kala-azar, and that less than 1 per cent. of uncomplicated chronic malaria cases give a definitely positive reaction; this has been demonstrated in non-kala-azar areas; so that for all practical purposes a positive reaction can be accepted as diagnostic of kala-azar. In the early stages of kala-azar the aldehyde reaction is not positive, so that a negative result cannot be accepted as final, and it is here that the quinine elimination test is of value.

As regards treatment, we cannot accept the statement that on an average the temperature disappeared after five injections; our own experience with 70 cases who were subsequently cured was that on an average the temperature became finally normal after the 15th injection. It is certainly true that patients begin to feel distinctly better after a very few injections, and this may have been accepted as evidence of the absence of fever. An average of 21 injections is very low, and we are surprised that in the face of the experience of others and in the absence of laboratory proof of cure Dr. Sur cared to risk giving such a short course of injections. The statement that "not more than 1 per cent. of the total cases were known to have relapsed within six months" may simply mean that he had no information as to the fate of the other 99 per cent. With the very inadequate course of treatment that the majority of the cases would have received the relapse rate must have been at least 20 per cent. This suggests that Dr. Sur did not enjoy such an intimate knowledge of the people of the neighbourhood as his earlier remarks might have led one to suppose.

No deaths are reported.

FEMALE MEDICAL AID IN RURAL AREAS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Is not the health of the women of India an important factor in the health of their children and of the race in general? If so, is it not the duty of every one—and especially of medical men—to care for them and to institute such arrangements as will ensure to the women of India proper medical attention, especially during such times as in confinement and in the puerperium?

In the towns and cities of India there are women's hospitals, lady doctors, trained midwives and trained *dhais*, but in the rural areas of India, comprising some 90 per cent. of the population, a trained *dhai* is hardly to be obtained within a ten-mile radius of any village. Yet the medical profession in India and our leaders of national thought and our wealthy merchants take but little note of such a situation.

The villagers in the rural areas are utterly ignorant; they know nothing of the preservation of health in either sex; they do not know what measures to take for a pregnant woman, nor where to seek advice and care in her confinement—supposing it to be even a normal one,—nor whom to consult after her delivery. The women of India will not be attended by doctors of the male sex. Hence they resort to quacks, and often spend large sums of money on devil appeasement by the *ojha*, or witch doctor. The results are terrible.

Amongst literate classes in the rural villages of Bengal it is customary to send women for their confinements to the towns where trained female medical aid is available. Amongst the illiterate and poorer classes those who have no means depend solely upon the mercy of Him who created the female. Still-born births, miscarriages, abortions, puerperal eclampsia,—all are termed works of a ghost or devil, and much money is expended in the satisfaction of the *ojha* or doctor of the ghost.

Can not trained *dhais* at least be supplied to every District Board dispensary in the rural areas of the country?—Yours, etc.,

S. P. NAG, V.L.M.S.

"PULSE DIAGNOSIS."

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—It is the custom among some of the Ayurvedic and Unani physicians of India to establish diagnosis by the pulse; on feeling the pulse of the patient, noting his posture and movements, noting his more obvious symptoms, such practitioners profess ability to reach an immediate diagnosis before the patient has yet begun to tell his history. Hence when a practitioner of the orthodox or Western system is called in, his inability to establish an immediate "pulse diagnosis" tends to disbelief in his professional ability. In fact many rural patients will refuse to disclose the history of their complaints on the ground that diagnosis is the business of the doctor, and not of the patient.

In rural practice, therefore, the trained medical practitioner has either to acquire the mysteries of "pulse diagnosis," or lose his practice.—Yours, etc.,

THE TEMPERATURE OF RECTAL AND INTRAVENOUS SALINE INJECTIONS IN CHOLERA.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I would feel much obliged if, through the medium of the *Indian Medical Gazette*, medical officers with experience of intravenous saline transfusion, could be induced to publish their views regarding the temperatures at which fluids should be introduced into veins. Authors of books seem to be somewhat at variance on this subject and even Sir Leonard Rogers has, I think, of late altered his views. As the best results can only be obtained by a combination of ideas born of experience, it would be in the interests of the profession to work on some settled and definite basis. The following are a few quotations from books:—

1. Colonel O'Meara's "Medical Guide for India," 2nd edition, p. 197—(Cholera treatment, revised by Sir Leonard Rogers).

Rectal temperature below 99°F. Flask temperature about 102°F.

Rectal temperature above 99°F. or over. Flask temperature about 100°F.

Rectal temperature over 100°F. Flask temperature about 99°F.

Rectal temperature over 102°F. Solution should not be warmed.

2. "Medical Annual" 1925, p. 86—(D. N. Banerjee). If the rectal temperature is 98°F. the saline should be at body temperature, and if the rectal temperature is higher the saline should be as many degrees below 98°F. as the rectal temperature is higher, and vice-versa. Sir Leonard Rogers commenting on this, says that in Calcutta where cholera cases occur mostly in the hot weather, the saline should rarely require to be warmed, while if the rectal temperature is 102°F. or 103°F., it may have to be cooled.

3. Manson-Bahr, 8th edition, p. 353—"The fluid in the containing bottle should be at a temperature of about 100°F. if the rectal temperature is below 99°F. If the latter is above 100°F., as there is risk from hyperpyrexia, the injection should be given at a temperature between 80° and 90°F."

4. Stitt, 4th edition, p. 236.—"If the temperature by rectum is about normal or slightly below, the temperature of the fluid should be 102° to 104°F."

5. Taylor, 12th edition, p. 176.—"The temperature of the fluid varies with the rectal temperature. If this is below 99°F. the saline should never be injected at above 98°F. for fear of producing hyperpyrexia. If the rectal temperature is 100°F. or over, the fluid should be given between 80° and 90°F."

From what I saw in Mesopotamia in 1916 and on the North West Frontier in 1919 and from my recent experience of over 200 intravenous saline injections I am led to believe that hyperpyrexia is not altogether dependent on the temperature of the fluid injected. Personally I have had no occasion to use fluid above 100°F. Fluid at this temperature I use when the rectal temperature is in the neighbourhood of 97°F. If the rectal temperature is 98°—99°F. the fluid injected is of about the same temperature. I have had rises of temperature under both conditions, but nothing alarming. A temperature of 104° or 105°F. can be promptly reduced by rectal iced saline. Apart from the suggestion that pyrexia after intravenous injections is due to causes other than the temperature of the fluids injected alone, idiosyncrasy also I think plays an important part. Quite recently I had three cases of rigor followed by a rise of temperature to about 103°F. after an intravenous injection of gr. ½ of iodine in 10 c.c. of sterile distilled water at about 86°F. This happened on four occasions consecutively in the same man, while others who had the same dose under similar conditions and at the same time showed no reaction.

While on this subject I would point out that the phrase "room-temperature" is misleading, as we have great extremes of temperatures in different parts of India and in the same locality during different seasons of the year. To work on a settled basis it would be advisable to avoid using this term and to state the temperature definitely in degrees.

One other point deserves notice. In the latest edition of Manson-Bahr I find that potassium chloride which has for some time now been omitted from hypertonic saline, is still advocated. I would be glad to have the views of your readers on this point also.—Yours, etc.,

V. J. LOPEZ,
Medical Officer.

ALIPURAM JAIL, BELLARY,
13th July 1925.

THE PROVOCATIVE DIAGNOSIS OF MALARIA.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I see in the *Indian Medical Gazette* for May 1925, an article by K. V. Raju on quinine plus alkalies in the treatment of malaria. In paragraph 7 of his conclusions he remarks that "if there is any drug which could be administered to drive parasites into the peripheral circulation, it would be of benefit to know of it."

There are two such methods of driving parasites from the spleen into the peripheral circulation.

(1) Adrenalin hydrochloride: 1/1000, 5 minims by hypodermic injection. This method was shown to me by Dr. Adamson, R.M.O., Kapurthala in 1922. A patient sent up as a case of suspected phthisis with a chronic temperature and suspicious apices of the lungs was given such an injection. Within an hour he had a severe rigor and parasites were found in the blood, which before was negative. This method is harmless.

(2) In an address and demonstration by Sir James Barr, C.B.E., F.R.C.P., F.R.S.E., delivered at the South West London Postgraduate Medical Association on October 16th 1924, he states:—"Dr. Abrams believed that the spleen was the chief manufactory of antibodies, hence in all infectious diseases he carried out what he termed splenic sterilisation. He first concussed between the third and fourth dorsal spines to dilate the vessels and get the germs out of the dark corners. He next concussed the seventh cervical and second dorsal spines to dilate the spleen and gather in the germs. He then, after two hours, concussed the second lumbar spine which contracts the spleen, and drives the germs and antibodies into the blood stream and so furthers the bactericidal action.

In cases of malaria he gave a large dose of quinine after concussion of the second lumbar spine.—Yours, etc.,

W. W. JEUDWINE,
LIEUT.-COL., I.M.S.

SIMLA,
22nd June 1925.

TREATMENT OF VARICOSE VEINS OF THE LEG BY AN OCCLUSION METHOD.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I have read with interest the above treatment advocated by Captain D. R. Kehar in your issue for last June. To me it appears a dangerous procedure from the possibility of embolus formation, unless the vein be "milked" before the ligatures are applied. I would like to learn further particulars of the technique and of its results through the medium of your journal or direct from Captain Kehar.—Yours, etc.,

A. BAYLEY-DE CASTRO,
Junior Medical Officer, Port Blair.

ANDAMAN ISLANDS,
6th July 1925.

THUMB IMPRESSIONS AFTER DEATH.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Is it possible for a medical jurist to tell, by looking at a thumb impression, whether it was taken during life or after death?

The question has arisen in connection with the following case:—A man who had no near relative living with him came under my treatment. As his condition became worse, some of his neighbours requested him to make a will leaving his property to a local temple. He refused and died a few hours later. It is now stated that a scheme was hatched among these people to have a will drawn up and to affix to it the thumb impression of the dead man. The scheme fell through because one of the persons concerned disagreed with it.

The question, however, may be of medico-legal interest.—Yours, etc.,

D. BHARADWAJA, L.R.C.P.,
L.R.C.S. (Edin.), L.R.F.P. & S. (Glas.).

GANGOH, SAHARANPUR DIST.,
26th October 1925.

A CASE FOR DIAGNOSIS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Can any of your readers enlighten me as to the possible diagnosis in the following case?

A female child, 4 years of age, was under my treatment for chronic malaria for some months. She appeared to be in good health after treatment for more than a month, the splenic enlargement having disappeared and her condition being good after a course of quinine and arsenic mixture.

On the morning of the 21st of July last, however, I was called in to see the child for fever and diarrhoea, which had started quite suddenly the previous night. The patient had had 3 or 4 soft stools during the night and the same number the next morning, the stools being small, yellowish or greenish in colour with some mucus. Her temperature on examination was 103°F., pulse very rapid and soft, respiration hurried. I prescribed medicine and gave instructions as to diet.

I was called again about midday the same day and found the child in a dying condition. She was reported to have passed two tarry stools an hour previously and to have become restless. I found her pulseless and cyanosed and she died shortly afterwards.

I am unable to account for the sudden melaena and the rapidly fatal issue.—Yours, etc.,

KHAGENDRA NATH CHATTERJEE, M.B.

CHINSURA,
18th August 1925.

(Note.—Possibly a fulminating infection with Shiga's bacillus, but the details given are insufficient to say.—EDITOR, *Indian Medical Gazette*.)

Service Notes.

APPOINTMENTS AND TRANSFERS.

In exercise of the power conferred by article 3 of the Statutes of the State Medical Faculty of Bengal, the Governor in Council is pleased to appoint Major-General R. Heard, C.I.E., M.D., R.H.S., I.M.S., to be President of the governing body of said Faculty, vice Colonel R. P. Wilson, C.I.E., V.H.S., F.R.C.S., I.M.S., resigned.

Lieutenant-Colonel J. W. D. Megaw, M.B., I.M.S., to be Honorary Surgeon on His Excellency the Viceroy and Governor-General's personal staff, vice Colonel R. P. Wilson, C.I.E., F.R.C.S., I.M.S., tenure expired.

Lieutenant-Colonel J. Cunningham, I.M.S., is appointed Director, Pasteur Institute of India, Kasauli, with effect from the 6th November 1925.

Lieutenant-Colonel W. R. Batyë, D.S.O., I.M.S., an Agency Surgeon, on return from leave, is posted, as Administrative Medical Officer in Central India and Residency Surgeon, Indore, with effect from the 12th November 1925.

Major W. O. Walker, M.B., F.R.C.S.E., I.M.S., is appointed as Civil Surgeon of Serampore, with effect from the forenoon of the 4th November 1925.

The services of Major J. L. Sen, M.C., I.M.S., are placed permanently at the disposal of the Government of Assam.

Captain B. G. Mallya, I.M.S., Superintendent, Alipore Central Jail, is appointed temporarily to act as Superintendent of the Juvenile Jail, Alipore, in addition to his own duties, during the absence, on leave, of Lieutenant A. P. Lopez, I.M.D., or until further orders.

Captain H. G. Alexander, F.R.C.S., I.M.S., Second Resident Surgeon, Presidency General Hospital, Calcutta, is appointed as First Resident Surgeon at that Hospital, with effect from the 1st November 1925, vice Major Hingston, I.M.S.

Captain S. A. McSwiney, M.B., F.R.C.S.I., I.M.S., Resident Medical Officer, Medical College Hospitals, is appointed as Second Resident Surgeon of the Presidency General Hospital, Calcutta, with effect from the 1st November 1925, vice Captain H. G. Alexander, I.M.S.

Captain H. E. Murray, M.D., I.M.S., is appointed to be Resident Medical Officer, Medical College Hospitals,

Calcutta, with effect from the forenoon of the 31st October 1925.

The services of Captain G. R. McRobert, M.D., M.R.C.P., I.M.S., are placed temporarily at the disposal of the Government of Burma.

LEAVE.

Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., M.D., F.R.C.S.E., I.M.S., Principal and Professor of Medicine, Medical College, Calcutta, and First Physician, College Hospitals, is granted leave for eight months, with effect from the 3rd September 1925.

Lieutenant-Colonel A. Leventon, I.M.S., Superintendent, Campbell Medical School and Hospital, Scaldah, was allowed leave for two years one month and eighteen days from 11th March 1923 to 28th April 1925.

Lieutenant-Colonel J. R. J. Tyrrell, I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months under the Fundamental Rules, with effect from the 12th November 1925.

Major H. H. King, I.M.S., an officer of the Medical Research Department, is granted leave on average pay for two months, with effect from the 6th November 1925.

RETIREMENTS.

Lieutenant-Colonel J. W. Illius, F.R.C.S.E., I.M.S., (under the Premature Retirement Rules), with effect from the 4th September 1925.

Major A. G. Coullie, F.R.C.S.E., 10th September 1925.

PROMOTIONS.

Captain to be Major.

J. W. Van. Reenan, M.B., F.R.C.S.E., I.M.S. Dated 31st July 1925.

Captain (now Major) J. Scott, D.S.O., O.B.E., M.B., I.M.S., to be acting Major from 19th July 1918 to 26th March 1920, whilst employed with the Egyptian Expeditionary Force.

NOTES.

FACULTY OF TROPICAL MEDICINE, BENGAL.

The following candidates passed the examination held on the 5th October 1925 and subsequent days at the Calcutta School of Tropical Medicine, for the certificate at the end of the short term course:—

1. Dr. Serajuddin Ahmed.
2. " Lakshmi Kanta Ally.
3. " Kumude Behari Banerji.
4. " S. J. Bellgard.
5. " Santi Prosad Chandra.
6. " Chrinjilal.
7. " Mannoo Lal Dave.
8. " Tapidas Maganlal Doctor.
9. " Ram Lal Madan.
10. " Suresh Chandra Mukherji.
11. " Shyma Charan Pal.
12. " Satyendra Prosad Sen Gupta.

LONDON MEDICAL EXHIBITION, CENTRAL HALL, WESTMINSTER, LONDON.

October 5th to 9th, 1925.

BURROUGHS, WELLCOME & CO.'S EXHIBIT.

The exhibit of Burroughs, Wellcome & Co. provided striking examples of progress in scientific pharmacy. A careful study of the products shown, both old and new, showed how thoroughly the needs of physicians are met and how efficiently this organisation keeps in touch with and renders practical the latest developments of progressive therapeutics.

Amongst the more recent additions were "Hypoloid" Bismuth Metal which places the potent spirillicidal properties of bismuth in isotonic glucose solution at the disposal of the physician. Another product of interest to the syphilologist is "Kharsulphan" for subcutaneous or intramuscular injection which provides a further simplification of arsenobenzol therapy.

"Iodicin" a product containing a high percentage of iodine in organic combination, in a pleasant, palatable chocolate base, is a very suitable means of administering iodine to children. Intensive iodine treatment, so successful in the hands of modern physicians, is, facilitated by "Tabloid" "Iodicin" capsules, each of which secures the administration of one grain of iodine in organic combination. "Ethidol" which contains 20 per cent. of iodine, is an allied product for use by injection into tuberculous abscess cavities, or for inunction in neuritis, rheumatoid arthritis, sciatica, etc. It possesses great localised penetrative power.

Interest was added to the exhibit by the display of "Wellcome" Brand vaccines, sera, tuberculins and diagnostic products, prepared at the Wellcome Physiological Research Laboratories and distributed by Burroughs, Wellcome & Co. Laboratory technique is provided for by the production of "Soloid" Micro-Stains, "Soloid" Nutrient Agar-agar, Opacity Tubes and numerous reagents of interest to the bacteriologist.

Production of pure chemicals and galenicals on an extensive scale is one of the major activities of the firm and the striking display of sodium salicylate of dazzling whiteness attracted attention to this typical "Wellcome" Brand product.

Every medical man, be he specialist or general practitioner, found much of value and interest to him at this :

OTALGAN.

An interesting product prepared by Messrs. H. R. Napp, 3 & 4, Clements Inn, Kingsway, London, W. C. 2, is "Otagan." In the treatment of otitis media, inflammation of the tympanic membrane and tympanum, and aural complications arising from coryza and other infectious complaints, the practice of using hot poultices, whilst relieving pain, does nothing to decrease tension and may increase the tendency towards mastoiditis. "Otagan" is stated to be phenyl-dimethyl pyrazolon, a 5 per cent. solution in anhydrous glycerine. It can be used without any previous preparation of the meatus, as the solution is stated to be completely anhydrous and the components freely soluble, whilst it should not be previously warmed. With the patient's head in the horizontal position, sufficient "Otagan" is dropped in to fill the auditory meatus, and no subsequent poultice or fomentation should be applied.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

THE INFLUENCE OF FOOD ON MORAL AND PHYSICAL DEVELOPMENT IN BRITISH INDIA.*

By V. B. GREEN-ARMYTAGE, M.D., M.R.C.P.,
MAJOR, I.M.S.,

Second Professor of Gynecology and Obstetrics,
Medical College, Calcutta.

LADIES AND GENTLEMEN,

I am going to attack the sacred edifice of the modern mother's castle, and what I am going to say to you is of such great importance to yourselves, your children, and those for whom you do social work that I trust you will forgive me if I am outspoken.

Alexander Pope two hundred years ago wrote that the proper study of mankind is man; but I think if he lived to-day he would have written "the proper study of mankind is woman"; for surely it is a wonderful example of the privileged illogicality of women, and a symbol of their sub-conscious sadistic cynicism that they are willing to see a vast amount of ill-health without raising a finger to alleviate it, or attempting to discover its origin.

You remember that during the great War between 1914 and 1918 the manhood of the nation was conscripted. It was then found that one-third of this manhood was what we describe as C. 3, i.e., diseased or defective. What was the cause of this? Was it our sanitation or our housing? No, for it is a well known maxim that man can thrive under any circumstances provided his food supply is good.

Was it our women who had failed to follow the dictates and laws of nature? Yes.

Was it indirectly due to ignorance and laziness on the part of our doctors or social workers? Yes.

Was it due to silence on the part of our pulpits and press? Yes, for not until it was too late was it realised that the era of this C. 3 population exactly coincided with the genesis of patent milk foods, bottled fruits and tinned meats.

The War broke out in 1914; the canned food era began seriously in 1894; but the War has at least taught us that the white man's curse is the predatory capitalist who preys on your credulity, ignorance and innocence, and broadcasts lies and flatulent nonsense on tins and hoardings which every mother accepts as gospel truth.

Verily a universal psycho-analysis is necessary for a state of mind that can be hypnotised by a tin or a hoarding, for such a state of mind

* An address given to the Central Welfare Clinic workers.

infers an inferiority complex, "a spare-the-trouble and spoil-the-child complex" which time and the War have proved utterly unworthy.

Someone once wrote "the hand that rocks the cradle rules the world". Do you think that he would write that to-day if he saw a bottle of X or Y or Z patent food in the cradle? No. Would he not prefer to write "the hand that rocks the cradle upsets the world and the baby"?

For cannot you all realise that despite the immense advances in medicine and surgery in the treatment and prevention of acute diseases, there is the undoubted fact that tuberculosis, cancer, appendicitis, pyorrhœa, enlarged tonsils, adenoids, flat foot, visceroptosis, constipation and glandular diseases are more common to-day than they were thirty years ago?

Cannot you see that there is a direct relationship between modern feeding and modern disease? The era of preserved food must go. We must get back to the common sense of our forefathers. You and I did not have patent food and canned meats as children, yet two-thirds of modern children do.

What of them and their posterity? We are their sponsors. Can you expect a normal mentality in a depleted glandular system? Can you expect other than Bolshevism, crime and sex complexes when instead of *mens sana in corpore sano* you have *mens insana in corpore malo*?

How many of you know anything of the feeding of a baby or child? If the least upset occurs, some fond friend or nurse or doctor comes along and suggests some patent food, and because Mrs. Jones' baby thrived temporarily and looks a bonny baby, you adopt the same treatment.

But you do not see that child at one, at two, at six, at puberty and early married life, as I do. I have records of thousands of such. You do not hear or see the anxiety and shame and pitiable distress.

You do not see the infant dying of acute diarrhœa. You do not see the child flat-footed, flat-chested, anæmic and pot-bellied. You do not see the case of delayed puberty nor the young wife who is unable to conceive; you do not hear the agony of the girl wife in labour, whose muscles and bones have not developed properly due to past defects in feeding; such agony is Nature's revenge on you as a mother and on your daughter through you. *Sunt lacrimæ rerum.* Do you realise that the enormous numbers of operations for tonsils, adenoids and appendicitis are the result of food faults and that some surgeons would starve if mothers fed their children correctly?

Do you know that six hundred of every thousand children born in Calcutta die within the first year of life, and of the four hundred

who survive one hundred are C. 3 at two, at six, at twelve and at twenty years. Do you grasp the fact that 50 per cent. of poor school children are foul-breathed, bad-toothed, big-tongued, flat-chested, flat-footed and pot-bellied? What is the reason? Their food—as I shall presently be able to prove to you.

Is it to be wondered at that the modern child is vicious, lacks enterprise, energy, and *vis a tergo* and is easily led astray when he grows up? Moreover when they do grow up they will be less virile and less capable of producing healthy children. Surely this is a state of affairs worth rectifying.

I shall not say a word against the masters and pastors of these children, for you all know how admirable they are in many instances, but what can they do when the soil is poor and the flesh is weak—however willing the spirit?

It is no good shutting your eyes and blinking facts. Doctors, clergy, press and social workers must combine to get at the home and the mothers. Practical propaganda and knowledge based on sure scientific data which has its proof in results, is the surest way of rectifying the moral and physical downfall which threatens Greater Britain.

We must teach the mother how to feed *before* the baby is born, and what to eat so that she may be able to nurse it or at least direct its feeding correctly—in order to ensure that the child obtains from infancy to adolescence the necessary vitamins and salts of iron, calcium, phosphorus, iodine, etc., from its food. Only by this means shall we see the future generation physically and morally growing up with those traits of character upon which we Britishers have hitherto prided ourselves.

The truth and nothing but the truth lies in our food supplies and depends upon substances we call vitamins, and in order to make manifest what I have been saying I append a digest of the subject. There will be “doubting Thomases” among you. If there are, may I remind them that every one of these symptoms and effects have been actually demonstrated and proved during recent years by experiment on men and animals? For instance, compare the Bengali, his physique and diet with that of the Punjabi; compare the Anglo-Indian with the pure European. For those of you who had relatives who were fighting or were made prisoners during the recent War, think of the diseases of the prisoners’ camps, of the diseases peculiar to the trenches; of the deficiency diseases of Mesopotamia; of the diseases and ill-health of modern France. What are we doing in British India to-day? Nothing! and yet all over the rest of the civilized world the press, doctors, clergy and social workers are waking up to these facts. It is astound-

ing that here in India with all its thousands of illustrations of diseases, our doctors, our press, our pulpits are either ignorant or silent as regards the vast importance of food and its bearing on one hundred problems both social and political in India to-day.

Perhaps you are not aware that two thousand years ago to-day Brutus killed Julius Cæsar for the sake of progress; would that so it might be also that I could this day kill the patent food and canned meat exploiter, who are the white man’s curse of the twentieth century, for then like Brutus I might paraphrase and say “it is not that I love India less, but truth more”.

Finally remember—“Where there is no vision the people perish”.

Conclusions.

“Vitamines are A, B, and C. Without vitamins we morally and physically slowly perish”.

“‘Ignorance in action’ exactly describes the scandalous state of dietetics in Greater Britain to-day. This ‘ignorance in action’ produces a C. 3 population, morally and physically degenerate.”

The average typical diet of the poor or ignorant to-day is made up of:—

Dried, patent or twice boiled milk, white-meat flour [Shakespeare’s “distressful (white-meat) bread”], milled polished rice, with twice-cooked meat or curry, and stale, or long-cooked vegetables.

Margarine, commercial butter or *ghee*, vegetable oil, lard, pork fat, sausages, or meat soup. A pudding of cornflour, sago, tapioca, pearl barley, arrowroot, macaroni, made with or without a custard or egg powder. Pastry or cake.

Tinned, so-called jam or marmalade, treacle, sugar or sweets, occasionally tinned meat or bottled fruit, biscuits, bananas, beetroot; washed down with tea, coffee, cocoa, or beer.

*Do you realise that not one single item of the above diet contains any vitamin?**

Can you expect other than moral and physical degeneracy?

Do you wonder that conditions such as rickets, anæmia, osteomalacia, pyorrhœa, constipation, enlarged tonsils, adenoids, cancer, tuberculosis, difficult labour, rheumatism, appendicitis, glandular diseases in childhood, puberty and adolescence, etc., etc., are more common to-day than previously?

Vitamins are absolutely necessary for the proper function-acting of all the vital glands and processes of the body, together with the assimilation of calcium, iodine, iron, magnesium, sodium, potassium and phosphorus from our food.

* This statement would not be accepted by most workers on vitamins as being strictly accurate; several of these articles contain appreciable quantities of vitamins.—Editor, I. M. G.

SHORTAGE OF VITAMINE A, CAUSES :—

- (1) Cessation of growth, or wasting.
- (2) Reduced resistance to infectious diseases, especially lung or gland infections.
- (3) Failure in the development of bone and teeth.
- (4) Anæmia.
- (5) Corneal affections.

SHORTAGE OF VITAMINE B, CAUSES :—

- (1) Loss of appetite or depraved appetite.
- (2) Gastro-intestinal derangements, indigestion, constipation, colitis and worms.
- (3) Loss of weight, weakness and lack of vigour.
- (4) Headache, anæmia and unhealthy skin.
- (5) Nervous and cardio-vascular depression.
- (6) Oedema.

SHORTAGE OF VITAMINE C, CAUSES :—

- (1) Sallowiness.
- (2) Loss of energy.
- (3) Fleeting pains in the limbs and joints in adults.
- (4) Growing pains in children.

Since such are the symptoms of shortage, they may be guarded against by partaking of those substances that Nature has provided, and against these substances—according to their degree of vitamins—I am placing 1, 2, or 3 plus marks:—

VITAMINE A.

Mother's milk	+++
Home-made butter	++
Fresh egg yolk	++
Green vegetables	++
Underdone meat	++
Fresh (fat) fish, e.g., <i>hilsa</i>	++
Cheese	++
Sweetbread, liver, kidney, heart	++
Beef and mutton fat	++
Fresh cow's or goat's milk	+++
Cod-liver oil	+++
Fresh game, snipe, pigeon, duck	++
Fish roe	++
Oysters	++
Shrimps	++

VITAMINE B.

Whole-meal or brown bread	++
Peas, beans, dhal, <i>brinjal</i> , ladies' fingers, etc.	++
Fresh egg yolk	++
Liver, heart, kidney	++
Sweetbread, brain	++
Nuts and fresh fruits	++
Yeast—(remember yeast extract, which we call marmite)	++
Porridge	++
Maize	++
<i>Chapati</i>	++
Corn cobs	++

VITAMINE C.

Fresh fruit—as oranges, grapes, lemon, tomato, etc.	+++
Raw green vegetables; especially, salads, celery, radish, onions	+++
Cooked green vegetables; especially spinach, cabbage, potato, turnips, etc. (if they are cooked not more than 15 minutes and no alkali is added)	++

THE BABY CINEMA IN PUBLIC HEALTH PROPAGANDA.

By A. W. TUKE, F.R.C.S.I.,

LIEUT.-COLONEL, I.M.S.,

MAY I call the attention of your readers, especially of those who are interested in rural hygiene, to the value of the excellent little Cinema Projector made by Pathé Freres of France, Ltd. It is quite likely that it is well known to many as it has been some months on the market, but are its educational possibilities recognised? Armed with this little instrument which only weighs a few pounds and a dozen or two films which could be carried in your pocket and only cost 3s. 6d. each, anyone with the help of the printed instructions could go into a village, be it in India or in England, and give an entertainment that could not fail to be of interest and amusement to old and young. No electric installation is necessary as the current is produced by merely turning a handle. To town-dwellers surrounded by a plentiful supply of cinema halls no doubt such a small picture might fail to appeal, but to those whose lot in life is cast in villages an occasional "Baby Ciné" show might be very welcome indeed. But it is not primarily with the object of amusing the rural population that I am concerned. It should be used for health education and for education in other subjects such as agriculture and natural history. Should you wish you can obtain a special camera and make your own films. Projector, camera and all you will need will not cost you £30 and the projector alone under £7 (in England). At

present no films bearing on the subject of health are obtainable for the Baby Cinema but I hope it will be possible to produce them in the near future. At any rate films suitable for use in India would be better if produced in India. Heaven knows there is plenty of scope there for health propaganda work in the East! To those who are possessed of a camera I would suggest such films as the following:—

1. Showing specimens of bad housing in towns and villages.
 2. Showing defective water supply.
 3. Showing milk production and sale.
 4. Showing how flies contaminate food.
 5. Showing the life history of the mosquito.
 6. Showing the life history of any common insects that carry disease.
 7. Showing how tuberculosis is spread.
 8. Showing a group of consumptives.
 9. Showing a group of syphilitics.
 10. Showing a group of children who have rickety deformities.
 11. Showing the results of chronic malaria, enlarged spleens, wasting, etc.
 12. Showing a model crèche for the children of working mothers.
 13. Showing a model food shop.
 14. Showing a model dairy.
 15. Showing a butcher's shop as it generally is and as it should be.
 16. Showing children doing physical drill, playing outdoor games, country dances, etc.
 17. Showing a group of blind persons.
- Around such films as these could be woven valuable little half-hour lectures which might help towards making life healthier in India.

More than half-an-hour performance I would not give. The active ingredient should be given with plenty of vehicle of an attractive taste.

A NEW METHOD OF ISOLATING AND CULTIVATING VIBRIOS FROM FÆCES, ESPECIALLY SUITED FOR THE DETECTION OF VIBRIO-CARRIERS IN FIELD WORK.

By J. W. TOMB, O.B.E., M.D., D.P.H.,

Chief Sanitary Officer, Asansol Mines Board of Health,
and

G. C. MAITRA,

CAPTAIN, I.M.S.,

Research Worker, School of Tropical Medicine and Hygiene, Calcutta.

(Mining Association Endowment.)

IN the course of the investigation into the bacteriology and epidemiology of cholera, which we are at present conducting in the Asansol Mining Settlement, we found that during the hot dry months of the year (February to June)—which also constitute the epidemic season in that area—vibrios were extremely numerous in the smaller village ground tanks much used by the inhabitants for bathing; the number of vibrios found in such tanks being approximately proportionate to the number of people using the tanks and inversely proportionate to the volume of water they contained. In very large "clean" tanks vibrios could only be found in close proximity to their bathing *ghats*.

From these observations we were driven to the conclusion that the vibrios found in the water of ground tanks were derived from human fæces and this conclusion was proved to be correct, for when several selected tanks were "closed" by one of us (under the *Regulations for the Prevention and Control of Cholera in the Asansol Mining Settlement*) and all bathing and washing of soiled clothing in the tanks prohibited, vibrios were found to have disappeared completely from the tanks after the lapse of ten to twelve days. On the order being withdrawn and bathing and washing being resumed, in all cases vibrios immediately reappeared. We therefore inferred that a considerable number of "carriers" of vibrios existed in the community, but when we attempted by ordinary laboratory methods of cultivation to demonstrate the presence of vibrios in the stools of those frequenting the tanks in question the results were so conflicting that we were forced to conclude, not that carriers were fewer in number than the experiment of prohibiting bathing and washing in the tanks referred to had led us to believe, but that the ordinary laboratory methods for isolating vibrios from stools were fallacious. We therefore set ourselves to discover a more reliable method of isolating vibrios from stools.

As our investigations had shown that ground tanks—particularly when polluted with a certain

degree of organic matter—were specially favourable to the growth and multiplication of vibrios, we decided to imitate Nature and to manufacture artificial ground tanks for our purpose. With this end in view we procured from the local bazar a number of earthenware *gumlas* (bowls), each of about one foot in diameter and nine inches in depth. These we lined thickly with tank mud and then filled them two-thirds full with stored raw tank water proved by frequent examination to be free from vibrios by intensive methods of cultivation. The water in these mud-lined *gumlas* was then again tested daily for over fourteen days to demonstrate the continued absence of vibrios. Into these artificial "ground tanks" small quantities of fæces were inseminated and the bowls left at room temperature (75° to 90° F.) in dry lockers duly protected from dust and direct currents of air.

In positive cases a pellicle formation on the surface of the bowls was often visible to the naked eye within three or four days, and on subculture of the surface layer on bile-salt-agar plates a rich growth of vibrios was demonstrable. Vibrios, although appearing in these artificial tanks about the second or third day after inoculation of fæces, did not however survive for more than three or four days in contrast to those in ground tanks which we had found to survive for as long as from ten to twelve days.

Since the chemical analysis of the water in ground tanks with high vibronic content usually revealed a higher percentage of organic matter than that in tanks not so heavily infested, we endeavoured to make up for the presumed deficiency of organic matter in our artificial tanks by the addition to them of a few c.c's. of a 1 per cent. solution of peptone.

The result of this was a great improvement, as vibrios when thus cultivated were found to multiply in the *gumlas* for a considerably longer period than was previously the case. Small quantities of sterilised urine were also substituted experimentally for salt-peptone with very satisfactory results.

About this juncture an article appeared in the *Indian Medical Gazette* for July 1925, p. 301, by Lieutenant-Colonel A. B. Fry, I.M.S., mentioning that the entrance of tidal water into fresh-water ground tanks in the deltaic areas in Bengal had long been observed to increase the virulence of cholera epidemics in those regions.

Acting on the hypothesis that the increased epidemic virulence thus observed was in all probability due either to the longer survival or the increased growth of vibrios in salt water, we added 1 per cent. salt to the water in the *gumlas* described above.

In this medium we found to our great satisfaction that vibrios grew readily and multiplied freely, but as earthenware *gumlas* were obviously unsuitable for general adoption in laboratories, we set out to discover which of the constituents of our artificial tanks could be eliminated without

loss of efficiency. After much experiment it became apparent that mud was unnecessary, that ordinary enamelled bowls could be substituted for the earthenware *gumlas*, and sterilised tank water for raw tank water.

Our artificial tanks therefore now consist of ordinary enamelled bowls of about 500 c.c. capacity containing 250 c.c. of sterilised tank water with 1 per cent. common salt; one c.c. of a 1 per cent. sterile peptone solution being added immediately before inoculating the medium with faeces.

For the collection and conveyance of stools to the laboratory we have adopted the following procedure:—

- Large test tubes (6 in. \times 1 in.) containing 10 to 15 c.c. of 1 per cent. salt solution are inseminated by means of a dry piece of wood or twig from a tree with a small quantity of solid faeces or cholera stool as the case may be. To the salt solution in these test tubes we have found that the addition of peptone is unnecessary, since 1 per cent. salt solution has proved to be a selective medium in which vibrios temporarily multiply whilst other faecal organisms are either held in check or tend to die out.

This method of collecting and transporting stools in the investigation of cholera in field work has proved of inestimable value, since the delay unavoidable in the conveyance of stools from distant villages to the laboratory proves in practice by this method to be an actual advantage, whereas by previously recognised methods such delay was almost certainly fatal to success.

On the arrival of the test tubes in the laboratory, or after 2 to 6 hours at room temperature, about six large loopfuls of the surface liquid in the tubes are inseminated into the enamelled bowls. The inoculated bowls are then left in a locker at room temperature, protected from dust and air. A few loopfuls of the surface layer of these bowls are tested daily for the presence or absence of vibrios by intensive methods of cultivation through peptone medium and subsequent plating out on bile-salt agar. Should vibrios not appear in the bowls within one week they are rejected. In positive cases vibrios as a rule appear within two to three days, and when abundant persist in the bowls for from two to four weeks.

This method of isolating vibrios from faeces and cholera stools has proved a great advance over all other existing methods, not only on account of its greatly increased accuracy but also on account of its cheapness; enamelled bowls, salt solution and a little peptone being all the materials required.

A NOTE ON THE INCIDENCE OF NEURO-SYPHILIS AMONG COLOURED RACES.

By O. A. R. BERKELEY HILL, M.D. (Oxon.),
MAJOR, I.M.S.,

Superintendent, Ranchi European Mental Hospital.

Of the more important diseases few have received of late so much attention as general

paresis. In October 1924, the International Bureau of Public Health in Paris made general paresis a special subject for discussion. Early in 1925 Dr. Kolb of Erlangen published in the *Zeitschrift für die gesamte Neurologie und Psychiatrie* an appeal for comparative statistics of general paresis on an international basis. Later, in the same journal, Dr. Kolb published the first instalment of the data he had received in reply to his enquiry. Although the information which I have been able to obtain has nothing like the same scientific value as that collected by Dr. Kolb, it may, all the same, be found to be of some little interest.

In 1922, at the request of Professor Emil Kræpelin, I issued a questionnaire composed by myself in the hope that the information it would elicit might be of some help in solving the riddle of general paresis, especially in respect to its incidence among coloured races. The questionnaire was as follows:—

(1) The incidence of G. P. I. among..... and.....

(2) The incidence of tabes among..... and.....

(3) Whether there are any records of data of any sort pointing to a recent increase in the incidence of either of these two diseases.

(It would appear from the information supplied to me by Dr. Dudgeon, the Medical Superintendent of the Khanka Asylum in Egypt that there has been such an increase of insanity among the native population.)

(4) If.....display a greater immunity to other diseases besides G. P. I. than is the case among Europeans.

(5) If affections of the skin and bones are more (or less) common in syphilis among..... than among Europeans.

(6) If syphilis is more (or less) prone to affect the brain and meninges among..... than among Europeans.

(7) If eye-symptoms are more (or less) common in cases of tabes dorsalis in.....than among Europeans.

(N.B.—In the blank spaces was inserted the name of the coloured people of the country to which the questionnaire was sent.)

Through the courtesy of the late Director-General of the Indian Medical Service, Sir William R. Edwards, K.C.I.E., C.B., C.M.G., M.D., F.R.C.S.E., my questionnaire was circulated to all Army Divisional Headquarters as well as to the Medical Department of each province in India. With the exception of the United Provinces, (whose Government would not consent to any attention being paid to my questionnaire), all the provinces and divisional headquarters throughout India treated my appeal with great consideration. The following is a summary of the information received from both civil and military departments to whom my questionnaire was sent:—

1. Dr. G. C. Ramsay, Labac Central Hospital, Cachar, Assam, states:—

Cachar is highly malarious. Syphilitic lesions are less severe than are in England. He has never seen cases of parasyphilitic lesions there. He seems to think that those born locally who survive malaria in youth and contract syphilis later in life are to some degree immunised against the toxins of the *Spirochaeta pallidum*. He further observes that the absence of G. P. I. and tabes dorsalis in malarious Assam and the "Vienna" treatment of these diseases by plasmodia has rather tended to confirm this belief.

2. Lieut.-Col. T. G. N. Stokes, M.B., I.M.S., Director of Public Health, Central Provinces, states:—

"Enquiries have been made in this province and the answers on the whole amount to this—G. P. I. and tabes are very rare among Indians in the Central Provinces."

3. Major H. W. V. Cox, I.M.D., Superintendent, Punjab Lunatic Asylum, Lahore, states:—

"From the records of this asylum during the years between 1907 and 1921, three cases of G. P. I. were admitted, of whom only one was an Indian."

4. Major W. S. J. Shaw, M.D., I.M.S., Superintendent, Central Lunatic Asylum, North Yeravda, Poona, writes:—

"I have seen over 20 cases of G. P. I. among Indians. There can be no doubt that G. P. I. exists among Indians, though it is nothing like so common as it is among Europeans."

5. Lieut.-Col. P. N. O'Neil, C.I.E., D.P.H., I.M.S., Superintendent, Lunatic Asylum, Calicut (Madras), writes:—

"Since 1897, out of total admissions of 1,243, only one case has been diagnosed as G. P. I. and then on insufficient grounds."

6. Lieut.-Col. J. C. S. Oxley, I.M.S., Superintendent, Lunatic Asylum, Nagpur, C. P. writes:—

"I am unable to find any case of G. P. I. recorded in this asylum for the last 20 years."

7. The late Major S. C. Chuckerbutty, I.M.S., Superintendent, Central Lunatic Asylum, Berhampore (Bengal), wrote:—

"In this asylum, no such case has been diagnosed by my predecessors. My experience of this place leads me to the belief that general paralysis of the insane cases undoubtedly exist among natives of India."

8. Lieut.-Col. E. A. R. Newman, C.I.E., M.D., I.M.S., Superintendent, Lunatic Asylum, Dacca, states:—

"No cases of G. P. I. have been recorded here."

9. Lieut.-Col. W. D. Ritchie, I.M.S., Superintendent, Lunatic Asylum, Tezpur, Assam, writes:—

"Searching the records of the last 23 years, we have failed to find a case of this disease. (G. P. I.)."

10. The Superintendent, Lunatic Asylum, Benares, writes:—

"There have been no cases of progressive

paralysis as far as the records of the asylum show for several years."

11. Sir Leonard Rogers, Kt., C.I.E., M.D., F.R.S., writes:—

"All my experience is post-mortem and we never got any post-mortem on G. P. I. or tabes during the twenty years that I was Pathologist in Calcutta. I remember Colonel Megaw showing a very early case of tabes at the Calcutta Medical Society, some years ago."

12. Capt. J. Rodger, I.M.S., Officer Commanding, Indian Station Hospital, Sitapur, writes:—

"There is no record of any cases of G. P. I. or tabes dorsalis in this hospital as having occurred during the past five years among an average garrison for the same period of 20 Europeans and 1,550 Indians."

13. Lieut.-Col. H. M. Brown, I.M.S., Officer Commanding, Indian Station Hospital, Lucknow, states:—

"No case of either G. P. I. or tabes among Indians has been admitted to this hospital between 1917 and 1922."

14. Captain M. Prasad, I.M.S., Karachi, Venereal Specialist, Western Command, writes:—

"The incidence of both these diseases (G. P. I. and tabes) among Indians is very small. During my experience of about six years of venereal practice in this country I have come across only two cases of tabes; one was a Hindu and the other an Indian Christian. The Superintendent of the Lunatic Asylum, Agra, in 1915 told me that he had about 5 Indians in his asylum suffering from G. P. I. I do not think Indians have any special immunity to these two diseases."

15. Lieut.-Col. C. A. Sprawson, I.M.S., Principal, Medical College, Lucknow, writes:—

"I have only (in 22 years' practice amongst Indians) seen one Indian case that I regarded as G. P. I. My students who go to Col. Overbeck-Wright at Agra for training in mental diseases are taught that G. P. I. is not uncommon in India. I do not see the cases. I have only seen one Anglo-Indian case of G. P. I. in India. I have only seen 4 cases of tabes dorsalis in 22 years in India, 3 of these were in Anglo-Indians and one in an Indian."

16. The Officer Commanding, Indian Station Hospital, Kirkee, states:—

"There have been no cases in recent years of either disease, (G. P. I. or tabes)."

17. The Officer Commanding, Indian Station Hospital, Ahmadnagar, states:—

"Neither myself nor the medical officers under my command have seen any cases of G. P. I. or tabes amongst Indians."

18. Dr. D. N. Ghosh, M.B., Teacher of Medicine and Pathology, Orissa Medical School, Cuttack, writes:—

"I cannot say I have seen a true or typical case of G. P. I. or tabes in the course of my 20 years' experience."

19. The Officer Commanding, Indian Station Hospital, Alipur, states:—

"Records of this hospital show that no case of G. P. I. or tabes has been admitted during the last four years. Both these diseases are exceedingly rare in Indians of this type (sepoys), whereas syphilis is common."

20. The Officer Commanding, Indian Station Hospital, Belgaum, states:—

"Out of 73 cases of syphilis admitted into this hospital during the last 8 months no case of G. P. I. or tabes has occurred."

21. The Officer Commanding, Indian Station Hospital, Deolali, writes:—

"No case of G. P. I. or tabes has been recorded during the past 5 years, although 240 cases were treated for syphilis."

22. Lieut.-Col. A. M. Harvey, I.M.S., Officer Commanding, Indian Station Hospital, Marine Lines, Bombay, writes:—

"176 cases were treated for syphilis during the last 5 years. No cases of G. P. I. have been shewn in my returns. It is possible that a case of G. P. I. may have passed through the hospital but any case shewing a positive Wassermann reaction would be returned as 'syphilis.' The same applies to tabes."

23. Lieut.-Col. R. K. Mitter I.M.S., District Medical and Sanitary Officer, Tanjore, writes:—

"No cases of G. P. I. among Indians and Europeans seem to have been recorded here of late years. Only stray cases of tabes among Indians have been recorded."

24. The Officer Commanding, Indian Station Hospital, Poona, states:—

"There is no record of any such cases (G. P. I. or tabes) as having been at any time admitted to this hospital."

25. Major A. Whitmore, M.D., I.M.S., Civil Surgeon, Rangoon (West) writes:—

"I am afraid that I can give but little assistance in the enquiry about G. P. I. among Indians and Burmese. I have had no experience, but I do not think that I would see such cases if they do occur. Of tabes dorsalis I thought for a long time that it did not occur at all in the native community, either in Indians or in Burmese. However, I am satisfied that the diseases do occur among Indians and Burmese, but how frequently or how rarely, I have no means of knowing. However, I consider the diseases are so rare that I could not feel sure of securing a typical case for demonstration purposes to the students during their 4th year of training."

26. Lieut. F. H. O'Leary, I.M.D., Offg. Superintendent, Lunatic Asylum, Rangoon, states:—

"Statistics regarding the incidence of G. P. I. amongst Indians and Burmese amongst the asylum population from 1911 are herewith forwarded. The nationality of the cases is only ascertainable from 1917 onwards, and from my personal knowledge and enquiries I am almost certain that only one European was admitted since 1917; 29 cases of G. P. I. were admitted during this

period, of whom 11 were admitted since 1917. Of these 7 were Burmese, 2 Chinese, 1 European and 1 Indian."

27. Major-General R. C. McWatt, M.B., F.R.C.S., I.M.S., then Inspector-General of Civil Hospitals, Punjab, states:—

"Replies received from civil surgeons and other medical officers in the Punjab show that G. P. I. and tabes are very uncommon in India."

28. Lieut.-Col. P. St. C. More, I.M.S., Civil Surgeon, Rawalpindi, writes:—

"During thirty years' experience, I have never seen a case of either G. P. I. or tabes among either Indians or Europeans."

29. Lieut.-Col. J. G. G. Swan, C.I.E., I.M.S., Civil Surgeon, Ferozepur, writes:—

"I have never seen a case of tabes or G. P. I. among Indians since I came to this country."

30. Lieut.-Col. D. M. Davidson, C.I.E., M.D., I.M.S., Civil Surgeon, Lahore, writes:—

"As far as I can judge G. P. I. is not common among Indians."

31. Lieut.-Col. H. Halliday, M.B., I.M.S., Civil Surgeon, Simla, West, writes:—

"I have not seen one case of G. P. I. amongst Indians during my services. I have seen one case of tabes in an Indian in the last 5 years."

32. Lieut.-Col. W. W. Jeudwine, I.M.S., Civil Surgeon, Jullundur, states:—

"No cases of tabes or G. P. I. have been seen by me among Europeans in this country. I have seen two cases of tabes in Indians."

I sent copies of the same questionnaire to various parts of the tropical and sub-tropical world outside the Indian Empire, namely to Egypt, South Africa, Nigeria, the Gold Coast, Ceylon, Hong Kong, the Federated Malay States, Japan, Madagascar, the Belgian Congo and the United States of America. In due course a great deal of information reached me, some of which was very interesting. The report of Dr. Dudgeon, Medical Superintendent of the Mental Hospital at Khanka, Egypt, was so important that I sent it at once to Professor Kræpelin, very unfortunately without taking a copy of it. The opinion of Dr. Dudgeon was to the effect that up to the outbreak of war in 1914 general paresis among the coloured population of Egypt was very rare, but since the war a good many cases of general paresis had been brought to his notice.

The following are summaries of reports received by me from the majority of the countries cited above:—

SOUTH AFRICA.

The Secretary for the Interior reports:—

1. The incidence of general paralysis of the insane among the natives of South Africa is low, amounting to about 1 per cent. of the total patients under care from the year 1921. It was stated by Dr. Greenlees, who was Medical Superintendent of the Grahamstown Mental Hospital in about 1906, that he had never known a case of general paralysis of the insane, but as early

as 1907 cases were found in the Pretoria Mental Hospital.

In the year 1918 there were 27 cases out of a total population of 2,609 patients under care. Dr. Dunston, the Commissioner, Mental Disorders, is of opinion that there has been no increase in the incidence of general paralysis during the last 10 years.

2. *Tabes* is rare among the natives of South Africa and not nearly so prevalent as among Europeans.

3. Natives display less immunity to other diseases than Europeans.

4. Affections of the skin and bones in syphilis are extremely common among natives; more so than among Europeans.

5. Syphilitic affections of the brain and meninges are not so common among natives as among Europeans and I would say that the native is less prone to such affections.

6. Eye symptoms in cases of *tabes dorsalis* are about the same in natives as among Europeans.

UNITED STATES OF AMERICA.

Surgeon-General B. J. Lloyd, Bureau of Public Health Service, Washington, in his letter dated the 26th December 1924, supplies the following table:—

Race and sex.	DEATHS IN THE REGISTRATION STATES (INCLUDING DISTRICT OF COLUMBIA) FROM:					
	Tabes dorsalis (Locomotor ataxia).			General paralysis of the Insane.		
	1923.	1922.	1921.	1923.	1922.	1921.
Negro:—						
Male ..	95	89	69	524	498	425
Female ..	21	27	18	202	209	185
Indian:—						
(North American)						
Male ..	2	2	—	6	4	—
Female ..	—	—	—	2	—	—
Chinese:—						
Male ..	5	5	4	11	13	16
Female ..	—	—	—	—	—	—
Japanese:—						
Male ..	—	1	1	7	6	5
Female ..	—	—	—	—	—	—
Other coloured:—						
Male ..	1	—	—	2	—	1
Female ..	—	—	—	—	—	—

NOTE.—The registration States formed 80.9 per cent. of continental United States in 1921, 84.2 in 1922 and 86.4 in 1923.

CEYLON.

Dr. R. L. Spittal, F.R.C.S., Wycherley, Buller's Road, Colombo, furnishes the following information:—

"In estimating the relative frequency of neurosyphilis among Europeans and natives, it must be remembered that the latter are much the more prone to neglect adequate treatment, to submit themselves to treatment only when the disease is well advanced, and to discontinue treatment as

soon as symptoms improve. The whole problem appears to me to be so involved that it defies solution without exact data. Therefore general impressions are more or less valueless, or even deductions from statistics that do not reckon with the factors I have mentioned."

The P. C. M. O. & I. G. H. Medical Department, Colombo, writes in his letter No. 3694 dated the 27th March 1924:—

"G. P. I., *tabes* and syphilis are probably as common among natives as among Europeans. There is, as far as I can say, no difference whatever in the way these diseases affect the different races. Any apparent differences are perhaps explainable by varying conditions of hygiene and diet."

Dr. L. D. Parsons, Medical Superintendent of the Colombo Lunatic Asylum, writes in his letter dated the 23rd February 1924:—

"As regards G. P. I. from 1914–1923 there have been 7 cases, all in males, of which 4 died here and 3 were discharged (of these 5 were not natives of Ceylon, one was a Singhalese and one a coast Moor)."

NIGERIA.

Dr. W. Alexander, Director, Medical and Sanitary Service, Lagos, Nigeria, W. Africa, in forwarding the summary of the replies received by him from medical officers throughout Nigeria, makes the following remarks:—

"I would like you to understand however, that over practically the whole of Nigeria only a small portion of the illnesses occurring are ever brought to the notice or under the treatment of the medical officers. For this reason it is impossible to generalise from such observations and statements as are given in the summary. For example it was thought at one time that cancer never occurred among natives, whereas increased confidence on the part of the natives has brought to light a considerable number and diversity of such cases.

The same experience applies to other diseases and may well apply to general paralysis of the insane and *tabes*."

Summary from the reports received from the Medical Officers of Nigeria.

1. The incidence of G. P. I. among natives of Nigeria and Europeans?

Three deaths from general paralysis of the insane are recorded in Lagos during the period 1918–1923. The Medical Officer, Lokoja states that he has seen "probably half a dozen cases of general paralysis of the insane among natives and non-natives of Nigeria in the last 13 years." The rest of the medical officers are unanimous in their replies that they have never seen a case of general paralysis of the insane among the natives of Nigeria.

There is no record of any case occurring amongst Europeans ordinarily resident in Nigeria. This may be accounted for by the fact that a European would be invalided out of the country as soon as his mentality became abnormal. It

would be very unlikely for any European to remain in this country with well-marked symptoms of G. P. I.

2. The incidence of tabes dorsalis among the natives of Nigeria and Europeans?

Here again replies are practically unanimous that cases of this disease among natives of Nigeria are extremely rare. Two such cases were described in the Annual Medical Report for Nigeria for 1922 by the medical officers of Port Harcourt.

3. Whether there are any records or data of any sort pointing to a recent increase in the incidence of either of these diseases?

All the replies are in the negative.

To the more or less chronically-infected condition of the inhabitants of Nigeria with the malarial parasite is attributed the absence of parasyphilitic cerebral manifestations.

4. If natives of Nigeria display a greater immunity to other diseases besides general paralysis of the insane than is the case among Europeans?

The majority of replies seem to indicate that the native of Nigeria has a greater amount of immunity towards the following diseases than Europeans display:—

(a) Malaria, (b) Yellow Fever, (c) Enteric Fever, (d) Carcinoma, (e) Trypanosomiasis, (f) Syphilis.

In the case of syphilis, only one or two medical officers call attention to this and attribute it to a certain amount of immunity handed down from one generation to another, because this disease is to a considerable extent left untreated amongst the natives of this country.

5. If affections of the skin and bones are more (or less) common in syphilis among natives of Nigeria than among Europeans?

Judging from replies received there seems to be no doubt in the minds of medical officers that visible manifestations of this disease are much more common in natives of Nigeria than in Europeans.

Is this to be wondered at? Syphilis is one of the best treated diseases in Europe to-day. It responds readily to treatment. Moreover the governments of different countries of Europe, realizing their responsibilities, have provided centres for free treatment so that the disease is well under control although the incidence per head of population may not be much less than it was, say, ten years ago.

Equally truthfully it may be remarked that the bulk of the native population do not readily come forward to receive the benefits which modern medicine can confer on them.

6. If syphilis is more (or less) prone to affect the brain and meninges among natives of Nigeria than among Europeans?

The bulk of opinion is that it is extremely rare to see natives of Nigeria suffering from para-syphilitic cerebral affections.

Less rare however is it to come across, from

time to time, cases, partial or complete, of paraplegia due to myelitis of the cord following on endarteritis obliterans of the vessels of the cord—a secondary syphilitic manifestation.

7. If eye symptoms are more (or less) common in cases of tabes dorsalis in natives of Nigeria than among Europeans?

Few cases of this disease have been recorded, two only within the last few years. In neither case was any record made of the eye condition.

FEDERATED MALAY STATES.

Dr. W. F. Samuels, Medical Superintendent, Central Mental Hospital, Tanjong Rambutan, Federated Malay States, in forwarding a list of the cases of general paralysis of the insane, writes as follows in his letter dated the 18th January 1924:—

“As to the incidence of general paralysis of the insane, I attach a list of the cases which we have had here since I opened the hospital in 1911.

As to race, it is almost invariably the Chinese who suffer from general paralysis of the insane. We have had a few Japanese, but I can only number one Tamil and one Japanese. There have been no Malays, although they are full of syphilis.

One must remember that the Malay has no troubles or worries of any sort. He can always get enough to eat, and so long as a Malay can eat and sleep nothing else worries him.”

In conclusion, I would like to refer to an article by Dr. Louis Wender, entitled “Psychoses prevalent on the Isthmus of Panama” published in the *American Journal of Psychiatry* in October 1923. Dr. Wender found that out of 414 consecutive cases admitted into the Corozal Hospital at Panama, between 1917 and 1918, there were 14 cases of general paresis among the coloured, and 10 among the white admissions. All the cases were males. Dr. Wender writes:—

“We included in this group all individuals showing marked defective judgment and reasoning powers, impaired memory for recent and remote events, grandiose delusions, depressions, excitement, and simple mental deterioration.”

“Neurological symptoms such as pathological deep reflexes, pupillary, gait and speech disturbances, were present in all these cases. The Wassermann reaction was positive in nearly all cases, the spinal fluid was positive, and the colloidal gold reaction of a paretic curve was present in all case. No female patients, either white

or coloured, suffering from this disorder, were admitted (at present several coloured females are here with paresis). At one time it was believed that the coloured race was immune to general paralysis of the insane; that this theory is not well-founded has been demonstrated. This theory was probably due to a failure to recognize this disorder in the coloured on account of the lack of grandiose delusions which were then thought to be characteristic manifestations of general paralysis of the insane. This disorder in the coloured, however, usually manifests itself in simple dementia. Of the 14 coloured male admissions here, there was only one patient who manifested grandiose delusions, and difficulty would have been encountered in making the correct diagnosis in the others if laboratory facilities were not available. The absence or the lesser preponderance of paresis among the females cannot be accounted for other than by the fact that the central nervous system of the female is very sensitive and unstable and breaks down much earlier from any toxæmia, such as the various types of infection, exhaustion psychosis, systemic syphilis, pellagra, etc."

KATAKAR OIL POISONING.

By SARASI LALL SARKAR, M.A., L.M.S.,

Civil Surgeon, Malda.

THE following occurrence shows that symptoms like those of epidemic dropsy have resulted in some cases from the use of adulterated mustard oil.

In a village named Attar, situated about 3 miles from the Bamangola Thana in Malda district, there occurred a few cases resembling epidemic dropsy, which on careful investigation were found due to the use of mustard oil adulterated with what is known as *katakar* oil. The cases occurred about three years ago in August, 1922. I intended to publish the reports of the cases, after ascertaining, if possible, something about the physiological action of *katakar* oil. But as I have not found this last to be possible I content myself with publishing the notes of these interesting cases from my note book, on the eve of my transfer from this district.

Katakar oil is the oil obtained from the mustard-like seeds of an Ayurvedic medical herb known as *Sialkata* which has multi-lobed thorny leaves and produces bell-shaped bright yellow flowers. The scientific name of the plant, as ascertained from the Curator of the Royal Botanical Garden, Calcutta, is *Argemone mexicana* Linn. an American weed that has run wild throughout the country, and is commonly known as the Mexican prickly poppy.

The following is a brief account of the occurrence resulting from the use of mustard oil adulterated with *katakar* oil.

Five or six days before the *Janamastami* festival, i.e. on the 9th or 10th August, the wife of Gamaroo, an oil-man, prepared some *katakar* oil,

as generally used medicinally for such skin diseases as scabies and eczema, in an oil-mill and the oil-mill was put aside without being washed or cleansed properly. Her husband, the oil-man was ignorant of this fact and he prepared some mustard oil in the same oil-mill, and this was taken for cooking purposes just before the *Janamastami* festival in the houses of the following persons:—

- (1) Ramchandra Mondal, (2) Pancha Mondal, (3) Moti Mondal.

The main ceremony and the chief pleasure of the *Janamastami* festival is frying cakes of the thick juice obtained from palm fruits in mustard oil and eating them. Thus a large quantity of this adulterated oil went into the system of the members of these families on the occasion of this festival, and all the members of these three households were affected.

In the house of Ramchandra Mondal, there was a boy aged 5 years and another boy aged 12 years, four adult females and seven adult males ranging from about 17 years to 40 years. All these were affected.

In the house of Pancha Mondal a boy aged 7 years and an adult aged about 42 years who were badly affected died subsequently. Besides this, three boys ranging from 10 to 13 years of age and one adult male of 52 years of age and two adult females were affected in the house.

In the house of Moti Mondal two boys aged 5 years and 7 years, three adult females, and two adult males were affected.

The date of the onset of symptoms was the 12th of August, 1922. The earliest symptoms were excessive spitting and vomiting, which was followed by disturbance of the bowels, followed by gradual œdema of the feet and legs. The affected persons placed themselves under the treatment of a village quack on the 21st of August, who treated them up to the 31st of August without benefit. Meanwhile the affected families were able to discover the fact that their disease was due to the use of adulterated oil on *Janamastami* day. On hearing about the epidemic, I wrote to the Medical Officer, Bamangola to send me any information which he possessed regarding the cases. He confirmed the fact that the outbreak of the disease which so resembled epidemic dropsy was really due to the use of adulterated oil, but the clinical description was very meagre in his report and is contained only in the following lines.

"I was called on to attend the cases on 5th September, 1922 and found the following symptoms.

- (1) Intense pain all over the body.
- (2) Inflammation of the leg from the toes to the hip.
- (3) Profuse diarrhoea in some cases, and in others severe constipation.
- (4) Slight fever running up to 101° F."

The cases were subsequently seen by the Medical Officer a month later, when he found these symptoms to be gradually subsiding.

I saw some of the cases a month later and found some amount of solid œdema left on the lower part of the leg and feet in some cases.

Two of the girls who went to buy oil from the oil-man, finding only a very small quantity of residual oil left, smeared the oil over their heads. On the night of the same day, the scalp was found to be inflamed with a burning sensation on the head and later on there was marked falling off of the hair.

Regarding the properties of the oil derived from the seeds of this plant, the following information is contained in the *Dictionary of Economic Products* by Sir George Watt, Vol. I, part III, pp. 306-309.

"The seeds yield a pale yellow, clear, limpid oil; used in lamps and medicinally in ulcers and eruptions.

There is also a great difference of opinion as to the action and dose of the oil of *Argemone mexicana*."

Postscript.—The following is a report on the analysis of *katakar oil* from the Director, Bengal Public Health Laboratory:—

THE TREATMENT OF BUBONIC PLAGUE WITH INTRAVENOUS INJECTIONS OF IODINE.

By A. C. BHARADWAJ, L.M.P.,

House Surgeon, King Edward VII Hospital, Benares.

PLAGUE has baffled all attempts on the part of medical men to discover any successful treatment to combat this fell disease, which has been ravaging tropical countries for more than half a century. Any method of treatment, therefore, that makes the future more hopeful by reducing the total mortality will be welcomed and appreciated both by the profession and by the general public, especially so as the treatment up to this time has been only a symptomatic one, without giving satisfactory results.

Sceptics may say that any drug that has not been scientifically tested is only empirical and cannot be approved as such; but iodine has proved its value and stood the test of time in various diseases. There is therefore no ground why its administration should be called empirical when administered to plague cases, knowing as we do that it acts by increasing the resisting power of the patient through leucocytosis.

Shortly after injecting a full dose of iodine intravenously the number of leucocytes in the peripheral blood is more than doubled and the temperature falls 2 to 3 degrees F. within a few hours.

No one has found iodine to be an antipyretic and the lowering of the temperature therefore indicates that the increased number of leucocytes overcomes the bacilli. There is no reason why such a useful drug should be discarded with contempt.

In Northern India the epidemics of plague have been extraordinarily severe and I tried from time to time all the treatments advocated in text-books, including excision of the glands, but they were mostly a failure. At last I came upon the article of Lieutenant-Colonel Jeudwine in the December 1923, issue of the *Indian Medical Gazette* and resolved to try intravenous iodine in plague cases. Prior to this I had been using it in cases of syphilis and septic ulcers with excellent results.

In 1923, an epidemic of plague broke out in Fyzabad district and thousands died within the short space of three months. The virulence of the disease was so great that the patients usually became delirious within a few hours and died within a few days.

The people were in the beginning reluctant to take intravenous injections, but when they saw and heard of severe cases recovering I had so much work that it became almost difficult to cope with it.

I treated about a hundred cases of plague in all with iodine injections and got about 80 per cent cures. The early cases were very easily brought under control; while patients in an advanced, delirious state and in the late stages of attack with fumbling speech and soft slow pulse did not do well. Most of the unsuccessful cases that gave the mortality of 20 per cent fall under this category. Dr. Naquvi of Jalalpur, a colleague of mine, also followed the same line of treatment with some material difference in the doses given and in the local treatment of the buboes. He also obtained very good results.

I use a solution of 18 grains of iodine with 36 grains of potassium iodine in 4 ounces of normal saline solution, and inject intravenously 5 to 10 c.c. of this in one dose every day for four consecutive days. This works out at an approximate dose of pure iodine of from $\frac{3}{4}$ to $1\frac{1}{2}$ grains and that of potassium iodide from $1\frac{1}{2}$ to 3 grains per day. Thus a maximum amount of iodine is injected directly into the blood stream without causing any untoward symptoms. People who injected tincture of iodine even in very small quantities report that in a certain number of cases thrombosis occurred, an experience unknown to me even after giving not less than six hundred injections of the drug in aqueous solution. In spite of

repeated injections of the solution into the same vein in several cases no thrombosis occurred.

I always insert the needle into the vein first, and when the blood gushes out, the nozzle of the syringe is mounted on to the needle and the contents emptied very slowly. Great care is always taken that not a single drop passes either into the coats of the vein or into the surrounding tissues; neglect in this respect at once sets up severe cellulitis and phlebitis which may go on to thrombosis of the vein.

One may here discuss the local treatment of the buboes as well. With the injections of iodine I at first injected 5 or 6 minims of pure carbolic acid into the bubo. This caused no pain but the tissues invariably sloughed and a foul ulcer resulted which took a long time to heal. Shortly after, while reading the report of the German Commission on plague, I came across mention of the great antiseptic power of mercury in destroying *Bacillus pestis*, and began to inject 1/16th grain of hydrarg perchloride in 2 c.c. of water into the bubo. This had the desired effect of reducing the size of the bubo to a half within 24 hours. The pain subsided and the general condition of the patient also improved much more quickly than with intravenous injections of iodine alone. There was no suppuration or sloughing. Later, I stopped injecting this solution into the bubo, and instead injected it subcutaneously into the lymphatic area drained by the particular group of glands in which the bubo had formed. There was no pain beyond a slight smarting at the time of injection and no sloughing of the subcutaneous tissue occurred. This procedure was found more effective than either of the two preceding methods.

With this treatment I always give the following mixture containing:—

Potass. Iodide	grs. v
Spirit Ammon. Aromatici	m. xx
Tinct. Strophanthi	m. ii
Spirit Vini Gallici	drs. ii
Aqua ad	oz. i

For one dose. To be taken every four hours.

This mixture is given from the very start, and no nourishment except water is allowed for the first three days. The patient does well on this medicine and has no desire for food. If the bowels are constipated, as they often are, I give an initial dose of 3 grains of calomel with 10 grains of sodium bicarbonate at bed time, followed by a Sedlitz powder the next morning. To patients who are not within easy reach of competent medical aid for injections or who are not willing to be injected I prescribed this mixture alone and it gives some 40 per cent of cures.

Summary.

1. Iodine injection in the form of aqueous solution is the best remedy hitherto known

for plague. It is harmless and acts by increasing the number of leucocytes.

2. Early cases are very easily controlled and 3 to 5 injections of 5 to 10 c.c. of the solution are sufficient to effect a cure.

3. The iodine treatment gives better results if it is supplemented with injections of pure carbolic acid into the bubo; or of 1/16th grain of hydrarg perchloride in 2 c.c. of distilled water into the lymphatic area drained by the group of glands in which the bubo has formed. No mercurial poisoning resulted from as many as 3 injections given consecutively. Besides, many medical men have injected as strong a solution as one per cent hydrarg perchloride into various veins without any ill effect.

4. No nourishment except water should be given for 3 days, and a mixture containing potassium iodide and stimulants should be given every 4 hours.

CORRIGENDUM.

In Dr. S. L. Bhatia's article on blood-sugar and sugar tolerance in our issue for last December, p. 568, under the heading Hypoglycemia, renal glycosuria, second paragraph, for:—"The urine may contain even 2 per cent of sugar when the blood-sugar content is less than 1 per cent," please read;—"The urine may contain even 2 per cent of sugar when the blood-sugar is less than 0.1 per cent."—Editor, I. M. G.

A Mirror of Hospital Practice.

THE EFFECT OF POSTERIOR GASTRO-JEJUNOSTOMY ON CHRONIC DUODENAL ULCER.

By W. C. PATON, M.C., M.B., F.R.C.S.E.,
MAJOR, I.M.S.,

Civil Surgeon, Coonoor.

We know that chronic duodenal ulcer is a very common condition in the Madras Presidency, whatever it may be in other parts of India. We know that posterior gastro-jejunostomy in the great majority of cases relieves the patient of all his symptoms. But we do not often have the opportunity of seeing the condition of the ulcer subsequent to operation. That is my only excuse for reporting the following case:—

Anthony, Indian Christian, aged 35, a butler, was admitted to the Lawley Hospital, Coonoor, on the 7th May 1925, with a typical history of chronic duodenal ulcer, extending over 12 years. Within recent months the symptoms of pyloric obstruction had been increasing. He was operated on on the 8th of May. There was found a very chronic ulcer on the anterior surface of the first part of the duodenum, with great thickening, and a considerable amount of stenosis.

Posterior gastro-jejunostomy was performed and the appendix removed. The dietetic

after-treatment consisted as usual of fluids only for seven days, followed by a diet of milk, bread, sugar, eggs, broth and a little rice for the rest of his stay in hospital. A bismuth and soda mixture was given after food when solid food was commenced.

He had no dyspeptic symptoms whatever after the operation, and was discharged on June 2nd with the wound apparently soundly healed. He remained quite free from dyspeptic symptoms, was eating his ordinary food, and improved greatly in general health, but for some reason he developed a ventral hernia. He was re-admitted for this on 25th October 1925, and operated on the next day. The hernia was repaired in the ordinary way, and the interest of the second operation lay in the opportunity to inspect the stomach and duodenum again. The first part of the duodenum was perfectly soft and of normal thickness, with only some small thin white patches on the peritoneal surface to mark the site of the previous chronic ulcer. The ulcer was apparently quite healed. The pylorus was perfectly patent and the stomach normal. The site of the anastomosis was healthy. Five and a half months after operation, therefore, in this case there was direct evidence that a very chronic duodenal ulcer had healed as a result of posterior gastro-jejunostomy.

A CASE OF EXTENSIVE FRACTURE OF THE SKULL WITH INJURY TO THE BRAIN. ESCAPE OF BRAIN MATTER, AND RECOVERY.

By A. S. DAWSON, L.M.P.,

Medical Officer, Thonze, Tharrawaddy District, Burma.

MA MYA SEIN, aged 8 years, a half-caste Burmese girl of the town of Thonze, was brought to the Civil Hospital, Thonze in an unconscious condition, said to have been knocked down by a motor lorry. She was taken to the hospital immediately after the accident at 11 a.m. on 31st October 1925. On admission the patient was in a comatose state; there was profuse bleeding from the left ear, the pupils were insensitive to light and half dilated; the pulse was slow but full.

The following injuries were found:—

1. An abrasion measuring 3 in. in length and 3 in. in breadth situated on the left temple.
2. A lacerated linear wound situated $2\frac{1}{2}$ in. above the right ear on the right parietal eminence $\frac{1}{4}$ in. in length, deep down to the skull which was fractured, the fracture extending anteriorly to the frontal bone, posteriorly to the parietal bone and outwardly to the temporal bone; here the line of fracture extended to the base of the skull.
3. A lacerated linear wound $\frac{1}{4}$ in. in length deep down to the skull, situated $3\frac{1}{4}$ in. above the outer extremity of the right eyebrow. The frontal bone was fractured, the line of fracture being continuous with the line of fracture mentioned under injury No. 2.
4. A lacerated wound directed transversely on the back of the head, 3 in. above the nape of the neck.

5. An abrasion on the right shoulder.
6. An abrasion on the right knee cap.
7. An abrasion on the back, over the right lumbar region.
8. An abrasion on the back close to injury No. 7.
9. An abrasion on the back close to the spinal border of the right scapula.
10. An abrasion on the right side of the chest below the right axilla.
11. An abrasion on the back posterior to the left axilla.
12. Fracture of the base of the skull on the left side as indicated by hæmorrhage from the left ear.
13. A contusion close to the left ear over the mastoid process.

The breathing was jerky and laboured. On admission first-aid dressings were applied after cleaning the parts thoroughly with antiseptics and ammonium carbonate given to inhale. A subcutaneous injection of "Hæmostyl," 8 c.c., was given. Within a few minutes the hæmorrhage from the ear stopped. The condition of the patient was carefully watched. An ice cap was also kept on the head till 4 p.m.

The same afternoon, at 4-30 p.m. the wounds on the head were explored by enlarging them under light chloroform anaesthesia. The depressed bones in the lines of fracture were elevated and the wounds were closed quickly as the condition of the patient at this time was such that prolongation of the operation might have led to fatal collapse. A rectal saline was administered and repeated every 4 hours during the day and night till the signs and symptoms of collapse abated. The next day, i.e. on 1st November 1925, the child began to be restless but regained the semi-conscious state at 3-hour intervals. During the conscious intervals nourishment was given, together with 10-grain doses of calcium chloride. The next day (2-11-1925) the patient became comatose and signs and symptoms of pressure on the brain were noted.

On 3rd November 1925, I decided to trephine the skull with a view to turn out clots and depressed bone. I opened the skull by excising the splintered bones: one of them measured $2\frac{1}{2}$ in. in length, 1 in. in breadth; the other was a sharp splinter $1\frac{1}{2}$ in. long and was found driven deeply into the brain tissue. At this spot the brain matter was escaping from a tear in the dura. The escaped pieces of the brain were removed, the other bigger pieces of the skull were also elevated and a lot of clot which was pressing on the brain was also removed and the parts were thoroughly cleansed. The wounds were closed leaving a small space for drainage.

The patient stood the operation very well as we had to administer very little chloroform, the patient already being in a comatose state. After this rectal salines were continued at 3-hourly intervals. The next morning the patient began to regain consciousness at intervals of 4 hours. On the 4th day after operation she regained consciousness. Nourishment and a stimulant mixture were given. Since then the patient recovered very rapidly although the injury was a very severe one, and all the wounds healed quickly. She was discharged cured on the 30th November 1925. The photograph shows her condition at the time of discharge from hospital.

Note.—The case is of interest as it was one of extensive fracture of the skull, involving the base of the skull and injuring the brain, with escape of brain matter. Operation was undertaken as a desperate and last resort.

My thanks are due to Dr. Lao Htin Poh, Civil Surgeon, Tharrawaddy, who kindly permitted me to perform the operation and also allowed his assistants to help me.

A photograph of the child, taken after cure is attached.

A NOTE ON THE TREATMENT OF AMOEBIC ABSCESS OF THE LIVER.

By H. CHAND,
CAPTAIN, I.M.S.,
Civil Surgeon, Kangra.

I READ with interest the account given by Lieutenant J. P. Arland, I.M.S., of a fatal case

the result might have been more favourable. I had a similar case recently admitted to the Civil Hospital, Dharmsala, of which particulars follow. My object in publishing this case is to draw the attention of medical officers to the advantage of the treatment of amoebic abscess of the liver by aspiration, combined with injections of emetine, instead of by open operation.

Mansukh, a Hindu male, aged 40, was admitted to the Civil Hospital Dharmsala, on 18th June, 1925, complaining of a painful swelling in the right hypochondriac region and fever with rigors, its duration being about 5 months.

Previous history.—He contracted dysentery two years previously.

Condition on Admission.—The patient was very anæmic, wasted and debilitated. There was a painful swelling reaching about a finger's breadth below the right costal margin. Temperature 101°F. He complained of evening rises of temperature and copious sweats. There was marked œdema of the feet. The differential leucocyte count was:—

Polymorphs	..	75%
Large monos.	..	22%
Lymphocytes	..	3%
Eosinophiles	..	—

A diagnosis of amoebic liver abscess was made.

Treatment.—On 20th June 1925, he was put on to daily hypodermic injections of emetine hydrochloride gr. 1. On 22nd June 1925, under chloroform the skin only over the most prominent part of the swelling was incised for about an inch. Potain's aspiration apparatus was then used and 4 pints of typically chocolate-brown coloured pus were

No. 60 Name, MANSUKH Age 40 Occupation AGRICULTURE Disease AMOEBIC LIVER ABSCESS.

of liver abscess in the *Indian Medical Gazette* for November, 1925. In my opinion, had he performed aspiration, combined with emetine injections, instead of operating upon the case,

withdrawn. One suture and a dry dressing were then applied.

From the attached temperature chart it will be observed that the patient had no rise

of temperature after the operation. In all eleven injections, each of 1 grain of emetine, were given.

The patient made an uninterrupted recovery. The swelling in the right hypochondriac region disappeared altogether and also the œdema of the feet. The patient became plump and healthy looking and was discharged cured from the hospital on 5th July 1925.

A CASE OF ACUTE HÆMORRHAGIC PANCREATITIS.

By K. M. NAYAK, L.M.S.,

Assistant Surgeon, Vellore.

THE patient, aged about 50 years, when in quite sound health suddenly took very ill on the morning of the 31st of October last. He was slightly adipose. The illness had a fatal termination and lasted for only 24 hours. He took very ill one morning and died the next. On the day of illness he got up as usual and had his early breakfast at 7-30 a.m. Since his bowels did not move satisfactory the previous day, he had taken a dose of Eno's "Fruit Salts" overnight and his bowels acted well that morning. At about 8 a.m., exactly half an hour after his meal, he felt acute excruciating pain in the epigastrium and vomited everything that he had taken. The pain was so severe and overwhelming that he was completely doubled up in 5 minutes and the pain kept coming and going every 15 minutes in severe paroxysms lasting for 5 minutes each time. The intensity was so severe as to distinguish it from that of appendicitis. The appendicular region and practically the whole of the right iliac and umbilical regions did not reveal any tender spots even on deep palpation, and the rectus muscle was not rigid. The abdomen was not board-like but tolerably soft in the beginning, but all the same, palpation was difficult as the patient was inclined to be fat and had a respectable paunch.

A perforated ulcer and passage of a gall-stone or a kidney-stone are the only common diseases giving such severe pains. The radiating character and the paroxysmal nature of the pain suggested either a gall-stone or kidney-stone. Absence of any previous similar attacks and absence of any crystals of urinary salts in the centrifugised urine led to the elimination of renal calculus. The fact that even gentle palpation elicited tenderness over the tip of the right 9th costal cartilage and that the radiating character of the pain was referred to the right shoulder blade and lumbar region, led to a tentative diagnosis of gall-stone being made. But even here there was absolutely no history of any previous attacks and he was not jaundiced. Gall-stones are said to be "tombstones erected

to the memory of typhoid bacilli" but the most careful enquiry did not elicit that he had ever suffered from typhoid fever.

General Condition.—The patient was very ill from the commencement. The pain was very acute, excruciating and exhausting. Vomiting, which was sudden and profuse in the beginning, continued for some time. His stomach was so intolerant as not to retain a teaspoonful of water or medicine. Ultimately it was limited to retching and bringing-up of only mucus mixed with saliva. His pulse was full, regular, bounding, 70 per minute, and remained like that till 4 a.m. on the morning of the 1st November, when it began to flag and became soft, small and thready. So much so that by 6 a.m. in the morning it was imperceptible and was sustained only by the administration of stimulants. In other words it was a *combined pulse*, hæmorrhagic and peritonitic. His abdomen, which was soft in the beginning, gradually became more and more distended and very tender all over. Though rigidity was not marked in the early stages, his abdomen became very rigid and tender all over later on, and was as hard as a solid block of wood. Though the abdominal tenderness was universal all over, gradual deep pressure in the epigastrium brought on excruciating pain. His temperature was normal throughout, or to be more accurate it was 98°F. In the later stages it was sub-normal and it never rose above the normal even by half a degree throughout the illness.

Treatment.—Though his bowels had moved satisfactorily that morning a soap and water enema was given straight off and was returned satisfactorily. Since appendicitis was ruled out of court from the very beginning morphia and atropine were given hypodermically and were repeated four times in the 24 hours, but had no effect on the pains at all beyond making the patient drowsy. The pain continued in the same intensity and was paroxysmal. The stomach was washed out at about 6 p.m. to stop the retching and this had some effect. Benzyl benzoate was administered thrice in 12 hours but had not the desired effect. Not being blessed with an x-ray installation in Vellore, a photograph could not be taken to clinch the tentative diagnosis of gall-stones. The nearest place where one was available was Madras, but the patient's condition at the end of 24 hours was such as to utterly prevent his removal to Madras either by train or motor. He would certainly have died on the way. Hence, after consulting another doctor and having obtained the patient's and his wife's consent, it was decided to operate on him immediately. He was put on the table at 9 a.m. He was practically dying, completely collapsed and slightly cyanosed in the face. The anaesthetist was

very nervous about his task. Saline hypodermoclysis was given in both axillæ. The patient was anæsthetised. The bladder was catheterised and as facilities existed on the spot the urine was again centrifugalised and the sediment showed nothing beyond hyaline casts.

Operation.—The operation was performed by Dr. B. Rama Baliga Ayl, B.A., M.B., C.M., District Medical Officer, Vellore, assisted by me. The usual gall-bladder incision was made on the right side commencing over the tip of the right 9th costal cartilage and extending downwards for about 3 inches. Not a drop of blood was visible till the peritoneal cavity was reached. When the peritoneal cavity was opened the first object that presented itself was the omentum, loaded with fat. When the structure was pushed aside the fundus of the gall-bladder peeped out and at the same time dark red blood-stained fluid (practically venous blood) began to well up from the wound. On collecting a sample of this fluid in a tablespoon fat globules were seen floating on the surface. Knowing that an acute pancreatitis is one of the causes of "acute abdomen" though rare, the presence of dark venous blood in the peritoneal cavity with fat globules left no doubt as to the fact of the case being one of the acute hæmorrhagic pancreatitis. At this stage of the operation the patient had a convulsion, his breathing became shallow and he expired on the table.

With the consent of his friends and relatives the incision was extended downwards, the appendicular and gall-bladder regions were thoroughly explored and found to present nothing abnormal. The peritoneal cavity was dried as far as possible and the intestines were found to be distended. The visceral peritoneum was inflamed, red and angry-looking and small white opaque spots of fat necrosis were visible in the omentum and mesentery. When the omentum and transverse colon were turned up, the whole of the transverse meso-colon, part of the mesentery and an extensive area of the posterior abdominal wall and the retro-peritoneal tissues were found to be infiltrated with blood. The pancreas itself was swollen and dark red in colour, due to infiltration with blood. The gland was removed for pathological examination which bore out the diagnosis of acute hæmorrhagic pancreatitis.

Discussion.—Acute hæmorrhagic pancreatitis, though rare, is a distinct clinical entity. Rapidly fatal termination of this disease is ample proof of the necessity for very early diagnosis and a wide knowledge of its signs and symptoms is quite essential. In my whole career of 18 years as medical student and as an assistant surgeon I have come across these cases only twice, once when I was a medical student in the year 1911 and now

a second time 15 years later. The symptoms make up a clinical picture which is quite clear and the diagnosis can in most cases be made sufficiently early. The image left on my mind by the above clinical picture is now so clear that I would not fail to recognise it a third time. Regarding the ætiology it is doubtless an acute infective process due to the presence of germs. It is said that it is not infrequently found in association with cholangitis and gall-stones which may be found blocking the ampulla of Vater. So our tentative diagnosis of gall-stone was not far from wrong. At any rate it is nearer the truth than to diagnose the condition as appendicitis or appendicular perforation. Unfortunately we could not hold a complete post-mortem.

In conclusion, I wish to express my thanks to Dr. B. Rama Baliga Ayl, B.A., M.B., C.M., District Medical Officer, Vellore, for having permitted me to publish these notes.

OPERATIONS ON OLD MEN.

By BANTA SINGH, M.B., B.S., D.T.M. (Bengal),
Jullundur City.

IN the presence of an accident or other affection threatening life, an urgent surgical operation may become necessary. In such cases the age of the patient may influence the prognosis, but not the necessity for immediate operation. In a patient suffering from strangulated hernia or depressed fracture of the skull or from some tumour of the body one would not hesitate to operate because the patient was aged.

Case.—An old man, some 80 years of age was admitted to the Phagwara Hospital, Kapurthala

State, in February 1922, with the following history. Twenty-five years previously he had noticed

that the left testicle appeared to be larger than the right. It increased very gradually in size, until ultimately a blister formed on its most dependent part; this ruptured, and foul smelling semi-fluid matter escaped of a brick-red colour. His condition on admission was as shewn in the photograph.

A diagnosis of adenoma testis having been made, he was thoroughly overhauled with regard to his heart, lungs, kidneys, etc., and appeared to be a fair operative risk. The operation was conducted in a very poorly equipped dispensary, with no assistant except a compounder, who gave chloroform anaesthesia, and as rapidly as possible to reduce risk. The parts were thoroughly cleansed, a tumour-like mass dissected out, and a drainage tube inserted into the dependent part. The patient made an uneventful recovery. Healing by granulation was naturally very slow in a patient of this age, but he was discharged cured on the 40th day.

The case illustrates the powers of recovery in an old man whose cardiac, pulmonary and renal systems were still in good order. A patient of 30 or 40 years of age with defective organs would have been a worse operative risk. Even in advanced age it is often possible to perform necessary operations; should a general anaesthetic be contra-indicated, a local one can be substituted; whilst a semi-sitting position can be substituted for the dorsal decubitus.

TWO INTERESTING CASES.

By S. K. GHOSH DASTIDAR, M.D., D.T.M.,

Assistant Surgeon, Orissa Medical School, Cuttack.

HADI SAMAL, Hindu male, aged 30 years, of Salepur village in Cuttack district was admitted to this hospital on the 13th July 1925, under Dr. B. C. Chatterji, D.T.M., Teacher of Medicine and Pathology and myself for irregular fever off and on for some time, marked enlargement of the liver, and scabies all over the body; there was slight oedema of the legs and round the ankles. He had had no treatment of any kind.

Physical examination: The liver extended three finger-breadths below the right costal margin, above to the 5th rib in the midclavicular line, and 7th rib in the midaxillary line; was slightly tender but hard and without any trace of jaundice. The spleen was not at all enlarged, but just palpable in deep inspiration. Other systems revealed no abnormality.

The blood was examined on the 15th July 1925: total leucocytes 10,000 per c.mm., polymorphonuclears, 70 per cent, large mononuclears 12 per cent, small mononuclears 18 per cent, no malaria parasite was found, but the aldehyde reaction was very strongly positive. The urine showed the presence of excess of phosphates, triple and amorphous, but no bile or other abnormality. The stool was normal and the microscopic examination revealed nothing abnormal. On the 20th the leucocyte count was 9,375 per

c.mm., and by that time the scabies was cured after active treatment with sulphur and zinc oxide ointment.

Thinking the case to be one of hepatitis, emetine hydrochloride gr. i was administered each day for 6 days from the 20th, and the liver began to shrink very rapidly, so that by the 6th of August it was hardly palpable and the leucocyte count fell to 5,625. The patient appeared to be progressing favourably.

All of a sudden a few days later he developed severe diarrhoea which did not respond to any medicine, as a result of which he died on the 13th. A post-mortem examination was conducted by me next morning. The liver was slightly enlarged and weighed 2lbs. 8 ozs.; was hard and cirrhotic; on section, of nutmeg appearance; the histological examination showed signs of chronic passive congestion. The spleen weighed 6 ozs. and was slightly fibrous. Smear examination of both the liver and spleen failed to show *L. donovani*. The intestine showed numerous small ulcers scattered throughout with a little congestion round them. The bladder wall was thickened and fibrous, and it contained thick pus-like urine with phosphatic deposit.

The points of interest in the case were:—

(1) the aldehyde reaction was strongly positive in a case of hepatitis, which was proved therapeutically by administration of emetine and subsequent fall of the leucocyte count to be such.

(2) the aldehyde reaction was positive even when no *L. donovani* could be detected in liver and spleen smears.*

II. *An Unusual Case of Ascending Pyelonephritis.*—Joykrishna Routh, a Hindu male child, 11 years old was admitted to this hospital on the surgical side on the 30th August, 1925, under Rai Bahadur Dr. J. Row, Teacher of Surgery, for severe agonising pain all over the abdomen, especially on the right side in front and behind with very irregular fever varying from 100° to 103°F and scanty micturition, lasting for more than a month.

Physical examination showed a very rapid pulse without any hurried breathing, peculiar abdominal facies, with absence of tympanites and of any swelling or tenderness at McBurney's point or any other part of the abdomen. On the 31st the leucocyte count was 25,000 per c.mm., with the polymorphonuclear cells 90 per cent and the urine was practically suppressed. The following day the leucocyte count fell to 22,875 per c.mm., but by evening the patient collapsed and died.

Post-mortem examination was conducted by me the next morning with very interesting findings. Nothing abnormal in the lungs and heart. The liver was deeply yellow and of nor-

* Failure to find the parasites after death is not conclusive evidence that the patient did not suffer from kala-azar.—Ed.

mal size, weight and consistency. A few flakes of fibrinous exudate covered the ileum near the ileocaecal valve and a small abscess with serpigenous margins was found in the posterior abdominal wall behind the ileum where the right ureter passed across behind it.

Both kidneys were embedded in big cavities filled with pus, and though apparently of normal size were completely disorganised and absolutely riddled with abscesses and necrotic areas. The ureters were thick, nodular and slightly dilated. A big stone (phosphatic), the size of a duck's egg completely occupied the cavity of the bladder leaving about one-fourth of an inch of space between it and the bladder wall. Besides it the bladder contained a few drachms of thick phosphate-laden urine.

Obviously death was due to two factors, septic absorption from the pus cavities and suppression of urine from ascending pyelonephritis due to vesical calculus.

I take this opportunity of expressing my gratitude to Major J. C. John, O.B.E., I.M.S., Civil Surgeon and the ward officers responsible for their assistance.

A CASE OF PRECOCIOUS SEXUAL DEVELOPMENT.

By M. G. RAMCHANDRA ROW, M.B., C.M.,
Chief Medical Officer, General Hospital, Pudukotah State.

I was consulted by his parents about a boy, aged about one year and ten months, who shewed unnatural development of the external genitalia. The boy was brought to me from a Chetty village about 21 miles from this town.

Family history.—The parents are Nagarthars by caste, are hale and hearty, with a family of one grown up daughter aged 17, and an elder brother of the patient, aged 4; all of them are of normal health and development. The patient, as shewn in the attached photograph, is rather short; he has a rude and rough behaviour, possesses a very shrill voice, unbecoming to his age. He can just talk in a way, but not distinctly. His brother, although 4 years of age, is terribly afraid of him on account of his rough behaviour.

It will be seen from the photograph that the genitalia, penis as well as testes, are highly developed, simulating those of an adult, whilst the pubic region is covered with long and dark hair. It was for this condition that the parents sought advice.

It has been recognised that cortical abnormalities of the suprarenal gland take effect upon the reproductive system, and that premature sexual development often accompanies tumours of the suprarenal gland. In the present case I cannot say what is the cause of this abnormal development; whether it is a pathological condition of the ductless glands, or only a case of hypersecretion of the glands.

My object in publishing the case is to receive suggestions from any of my brother

medical men as to the line of treatment to be adopted.

A HUGE SEBACEOUS CYST OF THE SCALP.

By P. PARAMESWARAN PILLAI, I.M.S.,
Assistant Surgeon, Thuckalay.

AZHAKAN, a low caste Hindu, aged 22 years, was admitted to the district hospital, Mavelikarai in September, 1924, when I was in charge of that hospital.

History.—The patient had had a swelling on his head from birth, which grew bigger in course of time until it reached its present size when it became slightly painful,—vide photograph.

Condition on admission.—There is a tumour about the size of a coconut without its fibrous coat, situated on the top of the head in front. It is soft, round, fluctuating, dull on percussion and irreducible. It can be moved slightly from side to side and from before backwards. There is neither pulsation nor respiratory impulse. There is slight tenderness on pressure and a feeling of heaviness on manipulation. The scalp over the tumour is thin but healthy. Whether there was any opening in the cranium, at or near the anterior fontanelle, could not be definitely

ascertained on account of the large size of the tumour.

Treatment.—Aspiration was performed under aseptic precautions when a thick, yellowish-white

sebaceous matter came out profusely and the tumour was found to have no communication with the interior. Through an incision along the median line the cyst was dissected out. The superabundant scalp was excised and the wound sutured with silkworm gut. The wound healed by first intention. The patient made an uneventful recovery and his appearance is now that of a normal person.

[*Note.*—The history of congenital origin, and its position in the mid line appear to suggest that the cyst may have been a dermoid cyst.—Editor, I.M.G.]

A CASE OF DERMOID CYST OF THE OVARY.

By KAILAS SINGH, L.C.P.S. (Bombay),

King Edward Hospital, Indore, C. I.

A HINDU woman named Mathurabai, aged 40 years, a Kunbi by caste, resident of Soada village in Khandesh, was admitted to the King Edward Hospital, Indore, on the 4th August, 1925.

She complained of swelling of the abdomen, difficulty in breathing on exertion, loss of appetite, and constipation.

Personal History.—Married 25 years previously. She had had two children. Both labours were normal. The last child was ten years old, i.e., she gave birth to this child when she was 30 years old. The menses were regular,

but for the last year there had been scanty menstruation. She was emaciated also.

History of the present condition.—One and a half years before the patient noticed a swelling in the right iliac region which was about the size of a small lemon. The swelling went on gradually increasing in size. There was no special complaint other than the swelling.

Present condition.—General emaciation present.

Abdomen.—There was generalised abdominal swelling, the left half of the epigastric region being more prominent. The consistency of the tumour varied in different places. It was hard in some places, in others soft and obviously cystic to the feel. It was tender at its most prominent part in the epigastrium. It could be moved from side to side. The surface of the tumour was smooth and regular.

The whole of the abdomen, except the extreme left flank and the right lumbar and iliac regions was dull on percussion.

On vaginal examination the uterus was a little backward and displaced to the left side and situated a little higher up than normal. Other systems normal.

The case was diagnosed as cyst of the right ovary and operation was performed under chloroform. As the tumour was very big, some of the fluid was let out first and then the tumour was removed. The fluid which came out was brownish yellow in colour, jelly-like and greasy in consistency. The fluid was 25 lbs. in quantity. The cyst proved to be one of the right ovary. To our surprise in the middle of the operation a bunch of hair about the size of an orange came out from inside the cyst.

The cyst was irregular in shape; more or less circular in outline. It weighed 38 lbs. Its external surface was shiny white, showing distinct loculations. There were no adhesions and no pedicle. In its interior were numerous loculations of varying size. Five of them were filled with a thick, yellow, semi-solid sebaceous matter and some hair. Other

loculi contained greasy pseudo-mucinous material. One of the latter loculi contained isolated matter together with a lump of hair about the size of an orange.

Points of interest about the case are:—

(1) The rarity of dermoid cysts of the ovary.

(2) They rarely attain such a large size.

The usual treatment of a post-operative abdominal wound was carried out and the patient made an uninterrupted recovery and was discharged cured on the 20th day.

The big mass of hair which came out from the inside of the cyst is shown in the photograph.

I have to thank Dr. S. K. Mukerjee, M.B., (Cal.), for helping me in getting this photograph, also to thank Lieut.-Col J. R. J. Tyrrell, M.B., I.M.S., for permission to publish notes on this case.

AN UNUSUAL CASE OF EXTRA-UTERINE GESTATION.

By H. CHAND,

CAPTAIN, I.M.S.,

Civil Surgeon, Kangra.

A HINDU female, aged 30 years, was sent to me by a lady working in the Canadian Mission Hospital, Kangra, for operative treatment:—

The patient was admitted to the Civil Hospital, Dharmasala, on 5th June, 1925.

Previous history.—The patient was a multipara and gave a history of previous normal pregnancies.

History of Present Illness.—About 5 years ago she became pregnant and pregnancy continued to full term; but no child was born. After a year and five months a sinus appeared near the umbilicus from which began to exude pus and later on pieces of bone. This went on till her admission to the hospital.

Condition on Admission.—There was a sinus near the umbilicus discharging extremely offensive putrefactive matter. A distinct swelling was visible between the pubes and the umbilicus. On exploring with a probe bones could be distinctly felt.

On palpation a swelling of the size of a small water-melon was felt, containing several pieces of bones. The patient's general health was fairly good and she did not show any rise of temperature.

Treatment.—On 6th June, 1925, under chloroform an incision was made over the swelling extending from the pubes to the umbilicus. Various bones of the skull, ribs, vertebrae, etc., were removed from the cavity. These bones were macerated and no fleshy part of the foetus was found. The cavity was entirely shut off from the general abdominal cavity. Coils of intestines could be seen behind separated by a very thin membrane. The

Assistant Surgeon examined the patient *per vaginam* at the time of operation and found the uterus not enlarged and entirely separate from the cavity containing the remnants of the foetus. The os uteri was semi-dilated but no finger could be introduced into the cervical canal. The wound was sutured and drainage tube inserted. The patient made a good recovery and was discharged from the hospital on 5th July, 1925, as cured.

Features of interest.

(1) The patient obviously did not suffer from any inconvenience apart from the very offensive discharge, as she did not seek medical aid for such a long time. She showed no signs or symptoms of general sepsis.

(2) Complete separation of the cavity containing the foetus from the general abdominal cavity and the generative organs.

(3) Putrefaction of all the fleshy portions of the foetus and their discharge through the sinus.

A CASE OF MYOMECTOMY.

By NALHADA PRASAD SHRIVASTAVA, L.M.S.,

M.B., B.S.,

Civil Surgeon, Seoni.

A WOMAN aged about 35 years, was admitted to the Seoni Main Hospital on 3rd January, 1925, for enlargement of the abdomen and bleeding from the vagina. The patient was married and a multipara. She had a history of excessive bleeding at each menstrual period for several years previous to the abdominal enlargement, anemia was pronounced, and the pulse rate was 116. Intermenstrual bleeding (metrorrhagia) had been in progress for about a year. The patient first noticed a tumour about the middle of the abdomen and at the level of upper border of the pubic bone. It had increased in size for about a year till it assumed the size of a child's head. There was no disturbance in micturition and no pain or pressure symptoms were complained of. A sense of heaviness in locomotion and after taking meals was the only symptom referable to the tumour directly. Profuse bleeding, general emaciation and progressive weakness were the chief complaints for which relief was sought.

Examination.—Abdominal inspection and palpation revealed a globular tumour in the mid-line of the abdomen extending to about 2 in. above the navel and impacted in the pelvic cavity. Its mobility was strictly limited. The tumour was smooth and uniform in feeling and hard in consistence, in remarkable contrast to an ovarian cyst. Percussion elicited a dull note over the tumour mass and the area of dullness was constant, irrespective of change of decubitus. On auscultation no sounds were heard.

Vaginal examination showed that the os was tilted upwards and forwards and was so closely jammed against the symphysis pubis that palpation was extremely difficult and no uterine sound could be passed. The uterine fundus which was retroverted was felt

posteriorly at a high level and the pelvic cavity felt filled up by the tumour mass.

The bladder was catheterised and showed lateral displacement to the right. The urethra was apparently elongated.

Diagnosis.—The differential diagnosis lay between (1) Pregnancy, (2) Ovarian cyst, (3) Broad ligamentous growth, (4) Malignant growth of the bladder, rectum or pelvic floor.

The duration of the growth, absence of uterine souffle, of foetal heart sounds and of foetal movements, the protracted and profuse bleeding, absence of uterine pains and of changes in the breasts easily eliminated pregnancy.

The consistency of the tumour, history of bleeding, restricted mobility and mid-line position of the mass eliminated ovarian cyst.

The mid-line position, unimpaired functions of the bladder and rectum and absence of pain and pressure phenomena eliminated the other possible conditions.

The diagnosis thus established itself as a "uterine tumour—probably myoma."

Operation.—On 10th January 1925 the abdomen was opened after a good deal of deliberation as the woman by virtue of protracted bleeding was a bad surgical risk.

A vertical incision was made from above the umbilicus to below the upper margin of the symphysis pubis, the tumour exposed, the intestines protected by abdominal towels, and the uterus with the tumour extruded through the wound as far as practicable. The round ligaments were found elongated and hypertrophied, the left ovary cystic and the uterine arteries hypertrophied. The uterus with the tumour presented a smooth and globular outline and the different parts of the uterus were impossible to discern.

A transverse incision was made across the most prominent part of the tumour along its anterior surface. On cutting through the capsule which was about 3½ in. thick a spherical tumour could be easily shelled out leaving a hollow shell and a globular mass attached to the lower end of the shell. On careful examination the lower globular mass proved to be a uterus of practically normal dimensions, and no other tumours could be palpated in its substance. Thus the tumour removed was a *suprafundal, single, subserous myoma*. The uterus was left undisturbed, the shell was excised to the utmost and the raw fundal area was closed by mattress sutures, bleeding carefully stopped, and the round ligaments left undisturbed; the left cystic ovary was excised and the abdomen closed after toilet of the peritoneum and leaving a pint and a half of warm normal saline in the abdominal cavity. The patient was placed in Fowler's position and made an uneventful recovery. The uterine bleeding stopped, the wound healed by first intention and the patient was discharged cured on 3rd February 1925.

The interesting features of the case are:—

- (1) Single myoma—as a rule they are multiple.
- (2) Protracted and profuse bleeding, which is rare in a subserous type of myoma.
- (3) Non-invasion of the uterine substance.
- (4) Non-disturbance of bladder functions though the viscus was laterally displaced.
- (5) Absence of pressure symptoms from pressure on the lumbar and sacral plexuses or the rectum.
- (6) Sterility of the patient though the uterine cavity was not invaded.
- (7) The existence of the tumour without any impairment of general health except in the late stages when bleeding became frequent and profuse.

A CASE OF SEPTIC ABORTION COMPLICATED BY *BACILLUS COLI* INFECTION.

By D. N. BUCHIA, I.M.S. (Bombay),

Late House Surgeon, Parsi Lying-in Hospital, Bombay.

THE publication on p. 295 of the issue of the *Indian Medical Gazette* for June 1925, of Dr. Wrench's case tempts me to describe a case recently under my treatment suffering from septic abortion, complicated by an infection with *Bacillus coli*.

Mrs. S. M., a Parsi lady, aged 27, multipara, was four months pregnant when sudden hæmorrhage set in on the night of the 14th May, 1925. In order to prevent abortion a full dose of morphia was given, she was put on a sedative mixture, and complete rest was ordered with a low diet.

Four days later she passed a blood clot with no accompanying pain or restlessness on the 18th May, and a four months' foetus was found lying in the vagina together with clots. As post-partum bleeding continued a further examination was made and a small piece of chorion removed with difficulty. She was now given a quinine and ergot mixture and the case left to nature.

The next morning a piece of placenta and membranes was passed naturally and her condition was good. On the third day after the abortion, however, fever ensued with a temperature of 101°F., pulse 120, headache, pain in the hypogastrium and restlessness. Intra-uterine examination shewed that there was still a small piece of placenta firmly adherent to the fundus uteri as if hanging on a tendon. Attempts to detach it failed, and the same afternoon there was mild shivering with a temperature of 102°F. A second attempt to remove it failed the next day, and her temperature rose to 106°F. with a prolonged rigor. A consultant was now called in who succeeded in detaching the piece of placenta, piecemeal, and only with great difficulty. No intra-uterine douche was given as he was opposed to such a procedure. A further rigor with a temperature of 104.4° ensued.

The next morning her condition was bad; she looked pale and puffy, temperature 103.4°; pulse 120; and the lochia quite suppressed. Poly-valent antistreptococcal serum was given, 100 c.c. in divided doses, each of 20 c.c. twice a day. An intracervical swab was taken and an autogenous streptococcal vaccine prepared, and injections of it commenced. After the fourth injection of vaccine the temperature became normal, pulse 96, and her condition was good.

Four days later, however, the temperature rose to 100.4° with pain and burning on micturition. The urine was withdrawn by catheter and yielded a pure culture of *B. coli*. An autogenous vaccine was prepared, and injections given every fourth day, together with an alkaline mixture and urinary antiseptics by the mouth. After seven injections recovery ensued and she is now in good health.

The interesting features of the case are:—
 (1) The very firmly adherent fibrous placental attachment, probably resulting from her previous chronic endometritis. (2) The repeated rigors with high fever. (3) A relatively low pulse rate in proportion to the high temperatures registered. (4) The urinary infection with *B. coli* as a sequel to the septic infection of the uterus. (5) Her recovery, although in such a grave condition, on autogenous vaccine therapy. I am of opinion that in such cases there can be no hard and fast rules, but that each case should be treated individually on its own merits. Even had the pregnancy proceeded to full term, she would probably have had to pass through a similar ordeal.

A CASE OF MADURA FOOT TREATED BY CHEMOTHERAPY. APPARENT CURE.

By F. J. PALMER, F.R.C.S.I.,

LIEUT.-COLONEL, R.A.M.C. (Retired).

As Madura foot has been hitherto regarded as incurable except by amputation, the following case may be of interest, and is published in the hope that those whose opportunities of meeting this disease are greater than mine may be induced to test this treatment. Madura foot would appear to be rare in Cachar, and the case reported is the second I have seen in three years. The first refused amputation and died some four months after being first seen.

T—D—an elderly Indian, appeared for treatment on 1st April 1925. The right foot was greatly enlarged, with swelling extending above the ankle, presenting a typical appearance, and discharging a watery, purulent, and foul-smelling fluid through several openings in the foot and sole, the largest of which was situated close to the insertion of the tendo Achillis. Pain on movement was marked, and the patient was carried to hospital. He also exhibited various evidences of old standing, half spontaneously arrested leprosy. A diagnosis of Madura foot in a chronic leper was made. No albumin was present in the urine.

As amputation was advised and rejected, it was decided to treat the case on the same lines as the writer's treatment of leprosy, and 3 grains of bismuth sodium tartrate (Burroughs & Wellcome) were given intravenously.

14-4-25. One discharging sinus drying up and almost closed. No difference at heel, where a slough can be seen at edge of the large sinus mentioned, the odour from which is still offensive. Urine shows a faint trace of albumin. Given 2½ grains bismuth tartrate intravenously.

A couple of dark brown, almost black, typical grains were seen in the discharge to-day and set aside for microscopic examination, but when called to an urgent case were, unfortunately, mislaid in my absence.

Three grains of bismuth tartrate were given intravenously on 9-5-25, 29-5-25, and 14-6-25. The sinuses closed, and pain was less marked. On the latter date,

a sinus which had closed reopened slightly. No albumin in the urine.

22-6-25. Grains 2½ bismuth tartrate intravenously.

30-6-25. Walking on foot a little. No albumin in urine.

10-7-25. Re-opened sinus near heel not completely healed. No albumin. Grains 4 bismuth tartrate intravenously. Patient was given ten one-grain pills of copper citrate, one to be taken daily before next visit. Three days interval to elapse after injection before commencing copper orally.

25-7-25. Sinuses closed. Swelling less. Walking a little. Grains 1½ of copper citrate intravenously. Ten grains of copper citrate in one-grain pills daily, to be taken as before.

11-8-25. Foot smaller, sinuses closed, skin wrinkling. Grains 1½ copper citrate intravenously; and ten grains of copper citrate in one-grain doses daily, as before.

25-8-25. Foot now nearly the same size as the other. No albumin. Grains 1½ copper citrate intravenously, followed by one-grain pills daily for ten days.

11-9-25. Tissue of sole now loose and flapping about. Grains 1½ copper citrate intravenously and one grain orally for ten days, after three days interval.

13-10-25. Foot almost the same size as the other and with all sinuses soundly healed. Can now walk a mile and feels much stronger. No anemia. Grains 3½ bismuth tartrate intravenously.

3-11-25. Grains 3 bismuth tartrate intravenously.

20-11-25. Shown at divisional meeting of Assam Branch, B. M. A. The Madura foot is apparently cured, but a swollen leprous toe remains. Ankle of normal contour. Can now walk about two miles.

It is to be regretted that the two diseases were here concomitant, but I have no doubt of the diagnosis as my acquaintance with leprosy and its manifestations is extensive. The discharge from the sinuses was microscopically examined on several occasions before they closed, and showed small globules staining deeply with gentian violet or methylene blue, but in which no structure could be distinguished. I am not sufficiently acquainted with the microscopic appearance of Madura foot discharge to know whether these are characteristic of the disease, but would surmise that these globules represent an early stage of development of the granules, which are such a characteristic feature of the disease.

The granules were only seen upon the one occasion noted.

It is somewhat difficult to appraise the effect of the two drugs used. The bismuth tartrate undoubtedly exerted a very powerful effect at first, but a slight re-opening of a sinus suggested that it might be somewhat losing its effect, though this might only have been the result of reaction. I therefore changed to copper citrate, which also appeared to have considerable effect.

The reactions that occurred in some of the leprous areas have not been touched on here.

It is hoped that others will try a method of treatment which appears most promising in a hitherto incurable disease.

A CASE OF INCIPIENT HEART-BLOCK.

By B. P. BANNERJI, M.B.,

285, Kalighat Road, Calcutta.

ON the 10th April 1925, about 5-30 p.m. I was called to attend a patient who had fainted. He was then just convalescent after an attack of chicken-pox which took place at Purnea, and had arrived in Calcutta the previous night.

Immediately before the fit he had been asleep. On being aroused by his brother at dinner time, he suddenly got up, gave a short scream and fell on his bed unconscious. Immediately afterwards I found him quite unconscious on his bed, and at first could not rouse him. His eyes were rolled upwards and deviated to the right, the pupils dilated but sluggishly reacting to light, and the corneal reflex almost lost. His face was a little cyanosed, and his breathing deep, sighing and almost stertorous.

After a few minutes epileptiform manifestations appeared, the limbs becoming stiff, with spasmodic contractions of the flexor muscles. The pulse was slow, 45 per minute, but the heart sounds normal.

The attack lasted nearly an hour, after which the patient gradually recovered, though exhausted; he complained of aching and pains all over.

The next day at about the same hour I was again called in to see the patient who had had a similar syncopal attack with convulsive movements, but this time lasting for a shorter time. His pulse varied from 45 to 50 per minute, whilst on auscultation extra-systoles could be elicited, though the cardiac sounds were normal.

Since then the patient has been in good general health, but with a tendency to similar syncopal attacks each evening at about the same hour. Owing to his nervous state, I had to keep a careful watch on him every evening for five days consecutively, the attacks however becoming more and more transient, and the patient gradually recovering, partly through psycho-therapy, partly by dietetics and eliminatives.

Ordinarily the patient is a stout, healthy looking man of about 27 years of age, sober in habits and newly married. About two years ago he had transient fainting fits on two occasions without any attributable cause. His father is subject to hysterical attacks, and one of his uncles had Stoke-Adams' syndrome some years ago, so there is some evidence of family predisposition.

The clinical picture of the case is very suggestive of block at the auriculo-ventricular bundle of Hiss which obstructs some of the auricular impulses during their transmission to the ventricle, causing bradycardia; whilst the syncopal attacks may be attributed to partial cerebral circulatory deficiency, but I cannot explain the occurrence of the attack at about the same hour every evening for several days. The subsequent history of the patient is uneventful and he is now in good health.

A PRELIMINARY NOTE ON TWO CASES OF ASTHMA TREATED WITH AN AUTOGENOUS VACCINE PREPARED FROM A GRAM-NEGATIVE BACILLUS ISOLATED FROM THE SPUTUM DURING THE ATTACK.

By A. J. NORONHA, I.M.S., M.D.,
Lecturer in Pathology and Bacteriology, B. J. Medical
School, Poona, and Pathologist to the Sassoon
Hospital, Poona.

THE writer does not at present wish to claim any specificity, causative or exciting, for the organism isolated until more cases of this nature are found. The results obtained however are so striking that a short note at this juncture will not be out of place.

Case 1.—Mr. V., L.C.P.S., then a student of the B. J. Medical School was admitted to the medical wards under Major A. G. Coullie, I.M.S. He had occasional attacks of mild asthma but his main complaint was breathlessness and cough. Major Coullie suspected early tuberculosis and granted the patient long leave. Before discharging him, however, he asked me to see if a vaccine would do him good as repeated examination for tubercle bacilli had proved negative. Frequent examination of the sputum showed the presence of a Gram-negative bacillus, non-motile, and not conforming in character to any known pathogenic organism. I was able to discharge Mr. V. quite free from his cough and bronchitis and from the asthmatic attacks to which he was subject. He has since passed his examination and has seen me several times, being now quite free from any symptoms.

Case 2.—Mr. G., sent to me for treatment by Major Garpurey, I.M.S., Civil Surgeon, Sholapur. I obtained a similar organism in this man's sputum. He had typical attacks of asthma and all treatment had failed to afford relief. Major Garpurey writes to me as follows about the case:—

".....I saw G. lately and he is greatly improved, has put on a stone in weight, and looks very fit. In this case at any rate... the results are very good."

These two cases are published for what they are worth, without any comment beyond the fact that the same organism was obtained in both cases.

A FATAL RESULT ASSOCIATED WITH FILARIAL INFECTION.

By B. N. GUPTA, O.B.E. (Military), M.B.,
Pathologist, Howrah General Hospital.

It would be of interest to obtain comments on the following case history:—

Ratnakar Pande, an Indian male, 25 years of age, was admitted to the Howrah General Hospital suffering from fever and jaundice. The fever was stated to be of five days'

duration and of intermittent type. The patient, on admission, was found to be unconscious, with icteroid conjunctivæ and pupils widely dilated. The extremities were cold; temperature 97°F.; pulse 68, soft and feeble; and respiration rate 20 per minute.

Nothing abnormal could be detected in the heart and lungs. The liver and spleen were not enlarged. On examination no albumin or sugar was detected in a specimen of the urine withdrawn by catheter. A blood film taken on the morning of his admission and stained did not shew any malarial parasites, but shewed microfilarie present. The film shewed leucocytosis, but no total count was done. A thick drop of blood, examined in the fresh state, shewed innumerable microfilarie.

The patient was treated for collapse, but did not revive, and died the same evening. A post-mortem examination was refused by his relatives.

The case is of interest from several points:—

(1) Filarial septicæmia not being known, whether there was some other septicæmic condition present, and the microfilarie simply came out into the peripheral circulation in the unconscious patient, as they would have done if he was sleeping.

(2) Or whether the case was one of infection with *Filaria diurna* with a concomitant septicæmic condition.

My thanks are due to the Surgeon Superintendent, Howrah General Hospital, for kindly allowing me to publish the notes on this case.

A CASE RESEMBLING INFANTILE CIRRHOSIS OF THE LIVER IN WHICH RECOVERY TOOK PLACE.

By N. GOPALAN, I.M.F.,

Sub-Assistant Surgeon, Municipal Dispensary,
Manambuchavady, Tanjore.

INFANTILE cirrhosis of the liver is a characteristic disease, occurring mostly among Hindu infants in Bengal and South India. It is not easily amenable to treatment and most of the cases rapidly terminate fatally. The following account is of a case which was noted by me, in which the infant recovered completely.

A male baby, aged about a year and a half, was brought to me two months ago, by a neighbour and friend of mine, a retired station master, with enlargement of the liver and spleen. The liver was found to be enlarged to three fingers' breadth below the costal arch, and the spleen was distinctly palpable. I was told that the child was getting thinner, but the abdomen more and more prominent. The child had become peevish in temper after the onset of the illness.

I was of opinion that the disease was fairly advanced and I plainly told my friend that the disease was not easily curable. The child was shown to many well known allopathic doctors, who were of the same opinion as myself as regards prognosis. The child was then taken away to Pudukotah to be placed under the treatment of a hydropathic doctor there. I saw the child a few days ago, and am glad to report that he has been almost completely cured.

The treatment adopted was as follows:—

The baby was placed every day both morning and evening in a tub of cold water, immersed as far as the chest, and the whole abdomen was rubbed gently with a wet towel for not less than 20 minutes. Whenever the child was constipated, an enema of half a pint of cold water was given. The diet was boiled sago in a semi-solid form, and Glaxo, at regular intervals. This process went on for a month and a half.

When the child was brought to me a few days ago, I was struck with the remarkable improvement in the health of the baby. The liver has receded and the spleen is not palpable. The child is now quite healthy.

I have treated a large number of similar cases with little or no success, and I may be permitted to state that I myself lost a daughter about 2 years old from this dire disease. In South India a large number of children die from it every year, contributing a fair share to the already high rate of infant mortality.

I request my professional brethren to try the hydropathic treatment, and report the results through the columns of your valuable journal.

[Note.—We have shewn Dr. Gopalan's notes to Dr. Sivapada Bhattacharji, Assistant Professor of Tropical Medicine, Calcutta School of Tropical Medicine, who has had considerable experience of the disease as seen in Calcutta. He remarks:—"Clinically the case appears to have been one of infantile cirrhosis, although there is no absolute criterion by which the diagnosis could be clinched, otherwise than at autopsy. In the early stage of the disease there is hypertrophy and an enlarged liver, but, as the case goes on, the liver gradually contracts, and diminution in the size of the liver is not a criterion of cure in all cases. The duration of the disease varies from 6 months to 2 years. The advanced condition of such cases shews a contracted liver, an enlarged spleen, jaundice, and a gradual development of ascites.

It is a curious fact that a change of environment—and in some cases even a change of house alone—may result in cure of the condition. In the present case reported on abdominal massage, a change of environment and a change of diet appear to have been the factors chiefly responsible for cure; the

hydrotherapy may have had but little to do with it."—Editor, *I.M.G.*]

A CASE OF PLEURAL EFFUSION WITH ABDOMINAL SYMPTOMS.

By M. G. RAMACHANDRA ROW, M.B., C.M.,

Chief Medical Officer, Pudukotah State.

I WAS called in early last June to attend a widow, by caste a *Chetty*, some 42 years of age, whom I found sitting with her legs extended and her back against a wall, struggling for breath. She was very pale and anæmic, and of thin and tall stature.

Her history was that she had gone on a pilgrimage some two months previously, and had had fever and cough subsequently. A smooth, painful swelling had been noticed in the epigastrium which had gone on increasing in size. She had been treated by various doctors, had had attacks of vomiting which appeared to have reduced the epigastric swelling, but for the previous 15 days there had been acute dyspnoea.

On examination the temperature was 104°F., pulse 135, respiration laboured and 35 per minute. A smooth bulging swelling was present under the left costal arch. The left side of the chest moved less freely than did the right. Percussion and auscultation shewed an enormous pleural effusion in the left side of the chest, pushing down the diaphragm and bulging in the left epigastrium. On cross-questioning she admitted to a history of stitch in the side at the commencement of the illness.

A first aspiration brought away some 80 ozs. of a straw-coloured fluid. A second, a week later, undertaken as there was still considerable dullness with impairment of the breath sounds, discovered no fluid. For some two and a half months she was treated with complete rest, tincture of iodine externally to the chest, a course of sodium morrhuate injections, colossal calcium, and other drugs. The diet contained broths and soups, milk, oranges and port wine.

The interesting feature of the case is that the patient referred all her symptoms to the abdomen and to the swelling in the epigastrium.

INTRAVENOUS IODINE IN PULMONARY DISEASE.

By V. J. LOPEZ,

Medical Officer, Alipuram Jail, Bellary.

As there are at present a number of advocates of intravenous iodine therapy, perhaps the following summary of a few cases treated by me in the Alipuram Central Jail from April 1924 to the end of July 1925, may be of interest, particularly so in view of Colonel Jeudwine's experience with this method of treatment.

I have been using iodine intravenously since 1922 in a variety of septic conditions with fairly satisfactory results, but for the present I shall confine myself to its use in pulmonary complaints.

Diseases.	Total admissions.	Treated with iodine intravenously.	Deaths.	Treated without iodine.	Deaths.
Pulmonary tuberculosis	81	61	13	20	15
Pleurisy with effusion..	27	9	0	18	0
Lobar pneumonia ..	38	12	0	26	4
Influenzal pneumonia ..	16	16	2

All the tubercular cases treated were unmistakable cases, no incipient or doubtful cases being included in this summary. Out of a total of 81 cases admitted to hospital 22 were transferred to other jails, 18 after a course of intravenous iodine and 4 prior to this. Later reports show that the latter 4 all died, whilst among the former only 3 cases proved fatal, the others making good progress. These are also included in the above table. Out of the 20 cases that did not receive intravenous iodine treatment, 15 died and the remaining 5 were released from jail and their further progress is not known.

Of the 33 "iodine" cases now remaining in hospital in this jail, 26 have so improved that to all intents and purposes they are cured. All symptoms have disappeared and it would seem that they are in fitter condition than they have ever been since admission to this jail about 4 years ago, the increase in weight varying from 15 to 35 lbs. Here I must mention that these men as well as those that did not receive iodine treatment had also a regular course of sodium morrhuate injections. The diet on admission to hospital was mainly of milk. Later, if digestion was not too impaired, eggs and soup were added. After the temperature had dropped to normal and the patient was allowed out of bed he was given "full diet" to which extras, such as milk, eggs, curds, butter, bread, soup, etc., were gradually added carefully.

Amongst the lobar pneumonia, pleurisy and influenzal pneumonia cases treated, only the very severe ones had intravenous iodine. In all these cases a routine examination of blood smears was carried out to eliminate the possibility of a malarial complication.

From amongst the milder cases of pleurisy two later developed pulmonary tuberculosis, but from amongst those that received intravenous iodine there have so far been no re-admissions.

duration and of intermittent type. The patient, on admission, was found to be unconscious, with icteroid conjunctivæ and pupils widely dilated. The extremities were cold; temperature 97°F.; pulse 68, soft and feeble; and respiration rate 20 per minute.

Nothing abnormal could be detected in the heart and lungs. The liver and spleen were not enlarged. On examination no albumin or sugar was detected in a specimen of the urine withdrawn by catheter. A blood film taken on the morning of his admission and stained did not shew any malarial parasites, but shewed microfilarie present. The film shewed leucocytosis, but no total count was done. A thick drop of blood, examined in the fresh state, shewed innumerable microfilarie.

The patient was treated for collapse, but did not revive, and died the same evening. A post-mortem examination was refused by his relatives.

The case is of interest from several points:—

(1) Filarial septicæmia not being known, whether there was some other septicæmic condition present, and the microfilarie simply came out into the peripheral circulation in the unconscious patient, as they would have done if he was sleeping.

(2) Or whether the case was one of infection with *Filaria diurna* with a concomitant septicæmic condition.

My thanks are due to the Surgeon Superintendent, Howrah General Hospital, for kindly allowing me to publish the notes on this case.

A CASE RESEMBLING INFANTILE CIRRHOSIS OF THE LIVER IN WHICH RECOVERY TOOK PLACE.

By N. GOPALAN, L.M.F.,

Sub-Assistant Surgeon, Municipal Dispensary,
Manambuchavady, Tanjore.

INFANTILE cirrhosis of the liver is a characteristic disease, occurring mostly among Hindu infants in Bengal and South India. It is not easily amenable to treatment and most of the cases rapidly terminate fatally. The following account is of a case which was noted by me, in which the infant recovered completely.

A male baby, aged about a year and a half, was brought to me two months ago, by a neighbour and friend of mine, a retired station master, with enlargement of the liver and spleen. hydrotherapy may have had but little to do with it."—Editor, *I.M.G.*]

A CASE OF PLEURAL EFFUSION WITH ABDOMINAL SYMPTOMS.

By M. G. RAMACHANDRA ROW, M.B., C.M.,

Chief Medical Officer, Pudukotah State.

I WAS called in early last June to attend a widow, by caste a *Chetty*, some 42 years of age, whom I found sitting with her legs extended and her back against a wall, struggling for breath. She was very pale and anæmic, and of thin and tall stature.

Her history was that she had gone on a pilgrimage some two months previously, and had had fever and cough subsequently. A smooth, painful swelling had been noticed in the epigastrium which had gone on increasing in size. She had been treated by various doctors, had had attacks of vomiting which appeared to have reduced the epigastric swelling, but for the previous 15 days there had been acute dyspnoea.

On examination the temperature was 104°F., pulse 135, respiration laboured and 35 per minute. A smooth bulging swelling was present under the left costal arch. The left side of the chest moved less freely than did the right. Percussion and auscultation shewed an enormous pleural effusion in the left side of the chest, pushing down the diaphragm and bulging in the left epigastrium. On cross-questioning she admitted to a history of stitch in the side at the commencement of the illness.

A first aspiration brought away some 80 ozs. of a straw-coloured fluid. A second, a week later, undertaken as there was still considerable dullness with impairment of the breath sounds, discovered no fluid. For some two and a half months she was treated with complete rest, tincture of iodine externally to the chest, a course of sodium morrhuate injections, colossal calcium, and other drugs. The diet contained broths and soups, milk, oranges and port wine.

The interesting feature of the case is that the patient referred all her symptoms to the abdomen and to the swelling in the epigastrium.

INTRAVENOUS IODINE IN PULMONARY DISEASE.

By V. J. LOPEZ,

Medical Officer, Alipuram Jail, Bellary.

As there are at present a number of advocates of intravenous iodine therapy, perhaps the following summary of a few cases treated by me in the Alipuram Central Jail from April 1924 to the end of July 1925, may be of interest, particularly so in view of Colonel Jendwine's experience with this method of treatment.

I have been using iodine intravenously since 1922 in a variety of septic conditions with fairly satisfactory results, but for the present I shall confine myself to its use in pulmonary complaints.

Diseases.	Total admissions.	Treated with iodine intravenously.	Deaths.	Treated without iodine.	Deaths.
Pulmonary tuberculosis	81	61	13	20	15
Pleurisy with effusion..	27	9	0	18	0
Lobar pneumonia ..	38	12	0	26	4
Influenzal pneumonia ..	16	16	2

All the tubercular cases treated were unmistakable cases, no incipient or doubtful cases being included in this summary. Out of a total of 81 cases admitted to hospital 22 were transferred to other jails, 18 after a course of intravenous iodine and 4 prior to this. Later reports show that the latter 4 all died, whilst among the former only 3 cases proved fatal, the others making good progress. These are also included in the above table. Out of the 20 cases that did not receive intravenous iodine treatment, 15 died and the remaining 5 were released from jail and their further progress is not known.

Of the 33 "iodine" cases now remaining in hospital in this jail, 26 have so improved that to all intents and purposes they are cured. All symptoms have disappeared and it would seem that they are in fitter condition than they have ever been since admission to this jail about 4 years ago, the increase in weight varying from 15 to 35 lbs. Here I must mention that these men as well as those that did not receive iodine treatment had also a regular course of sodium morrhuate injections. The diet on admission to hospital was mainly of milk. Later, if digestion was not too impaired, eggs and soup were added. After the temperature had dropped to normal and the patient was allowed out of bed he was given "full diet" to which extras, such as milk, eggs, curds, butter, bread, soup, etc., were gradually added carefully.

Amongst the lobar pneumonia, pleurisy and influenzal pneumonia cases treated, only the very severe ones had intravenous iodine. In all these cases a routine examination of blood smears was carried out to eliminate the possibility of a malarial complication.

From amongst the milder cases of pleurisy two later developed pulmonary tuberculosis, but from amongst those that received intravenous iodine there have so far been no re-admissions.

Dosage and Preparation of Iodine.—A watery solution of $\frac{1}{2}$ to 1 grain of iodine with twice this quantity of potassium iodide in 10 c.c. of sterile distilled water has been the usual dose. None of the cases reported above received more than one grain of iodine at a dose. The B. P. tincture was never used.

Intervals.—In the case of tubercular patients injections were given every fourth day. Six injections were reckoned as a "course." In the majority of cases one course was all that was necessary; nine of the sixty-one cases treated required a second course after an interval of 2 to 3 weeks and 3 cases had 3 such courses.

The cases of pneumonia, etc., treated received the injections every day or every second day according to the severity of the case. Three injections as a rule sufficed, the dose always being $\frac{1}{2}$ grain of iodine.

Technique.—This is the same as for other intravenous injections, choosing a fairly large vein at the bend of the elbow or in the forearm, and using a 10 c.c. all glass or "Record" syringe. A really sharp pointed needle is a necessity as a very large proportion of the difficulty and failures encountered is due to blunt needles.

The injection of the fluid after the needle has entered the vein should be slow, as in the case of other intravenous injections. Pain is not often complained of.

Most of my cases were bedridden patients but a few that were up and about were kept in bed for a few hours after the injection. No special preparation of patients prior to injection was found necessary.

Reaction and Complications.—The percentage of cases that show any reaction at all is very small. Out of about 200 patients who had intravenous iodine during the last 18 months only five had reactions (2 of pulmonary tuberculosis, 2 of pneumonia and 1 of syphilitic disease of the testis); viz., a rigor within $\frac{1}{2}$ to 1 hour of injection, with a rise of temperature varying from 101° to 103° . This generally fell to normal within 2 to 3 hours. No special treatment was indicated. Rest in bed and a couple of blankets were all that was found necessary. I am unable to ascribe any reason for this reaction as all the injections were given under similar conditions. Idiosyncrasy probably plays an important part, as these men had the same types of reaction after every succeeding injection.

I have so far had no cases of iodism in spite of the fact that the intervals between injections were comparatively short.

I have had no cases of thrombosis worth mentioning and have been able to use the same vein repeatedly. This may be due to the fact that when dealing with male adults I have been fortunate in getting fairly large and prominent veins. There is a belief in certain quarters that use of the B. P. tincture instead of a watery solu-

tion tends to bring about thrombosis, but I have had no personal experience of this.

CASES OF FOREIGN BODIES IN THE NOSE AND EAR.

By K. N. PRADHAN, I.M.S. (Bombay),
Mayo Hospital, Nagpur.

Case 1.—A male child, aged 4 years, was brought with the following history:—Denied all history of having put a foreign body into the nose, but had suffered from a purulent nasal discharge for the past four or six months. Occasionally there was bleeding from the nose, but no offensive odour. Swelling on the left side and in the region of the left antrum had been noticed. Treatment with hot fomentations, hydrogen peroxide and other irrigations had effected no relief. Examination with the nasal speculum shewed both antra quite clear. The pupillary reflex could not be seen, but a definite dark shadow was seen on the floor of the left nostril. With a probe a tamarind seed in rather a crushed condition was evacuated. There was smart hæmorrhage after its removal, but this stopped on sponging the child's face with cold water. Bare bone could be felt in the floor of the nose, but the condition cleared up well on a simple liquid paraffin spray. *Comment:* in any case of unilateral purulent nasal discharge in the case of a child, think of the possibility of foreign body in the nose.

Cases 2 and 3.—Two patients from different families, one a boy of 5, the other a girl of 4, came complaining of offensive, purulent discharge from the right nostril. There was no history of bleeding or of swelling of the face. Also no history of the insertion of a foreign body. From both, however, pieces of betel nut were extracted. In both cases transillumination shewed a dark spot in the floor of the nostril, but the pupillary reflex was not seen.

Case 4.—An elderly compounder was standing on a rainy evening near a powerful electric lamp around which many moths had collected. He suddenly felt a peculiarly painful sensation in his ear. The next instant this stopped and then recurred. On being called in I was alarmed to see the agony which he was suffering and his violent shaking of the head. On inserting a speculum I made out a small insect trying to climb up the wall of the tympanum. The membrane appeared to be normal, and a drop of glycerine was instilled. The patient then screamed and the next instant the living insect dropped out of the ear. In its struggles apparently it tried to scratch deeper and deeper into the membrane. The next day there was deafness and inflammation of the whole tympanum; no perforation was seen, but it took a week before the drum became normal again, whilst a serous discharge was present for some days.

Indian Medical Gazette.

FEBRUARY.

THE ALKALOIDS OF CINCHONA.

THE Medical Research Council has just issued a report of the findings of a committee which was appointed in January 1920 for the purpose of investigating the action of the cinchona derivatives on malaria.

The members of the committee were Dr. Andrew Balfour, Lt.-Col. S. P. James, I.M.S. (retd.), Dr. H. H. Dale and, for part of the time, Major H. W. Acton, I.M.S., who had to resign from the committee on his return to India. The reason for the formation of the committee was the publication by Major Acton of evidence which pointed to quinidine and cinchonidine being definitely superior to quinine in the eradication of benign tertian infections. The committee dealt specially with the relative merits of quinidine bisulphate and quinine bisulphate and employed specially purified samples of these drugs. The committee was unable to test the value of the two drugs in bringing about complete cures, as they had not the unique opportunities which Major Acton enjoyed of having a large number of malaria patients under complete control in a non-malarious place. For this reason, their findings are not strictly comparable with those of Major Acton. They claim that their experiments were more satisfactory in one respect than those of Major Acton, in that his patients were men who had relapsed after a previous full course of quinine and that the observed greater efficacy of quinidine might apply only to patients who had previously been treated by quinine, while it might not be applicable to the use of quinidine in the general treatment of malaria.

The findings of the committee were based on observations on the action of the two alkaloids in causing disappearance of the parasites during an acute attack.

Reports were received:

(1) From Colonel Harvey who treated 7 cases of benign tertian malaria with quinine bisulphate, 10 grains for 70 kilogrammes body weight. The drug was dissolved in dilute sulphuric acid, one dose was given before breakfast and one before the evening meal.

Eleven patients were treated with quinidine bisulphate used in the same way. The average time of disappearance of the parasites was 3.1 days in the case of quinine, while it was 4.4 days in the case of quinidine. There

was vomiting in 4 of the patients treated with quinidine, so that it is likely that absorption of the drug was incomplete: hence the observed difference in time of action does not constitute satisfactory evidence.

(2) From the Civil General Hospital Khartoum.—In 27 cases of sub-tertian malaria, no significant difference could be detected between the two drugs. In 19 cases of benign tertian, the disappearance of the parasites took place in 3.5 days with quinine and 4.6 days with quinidine.

(3) From the Public Hospital, Georgetown.—The records show no appreciable difference between the two drugs.

(4) From the Superintendent Medical Officer, Kampala.—The report is not capable of analysis on the same lines as the other reports.

(5) By far the most complete report was received from Dr. Fletcher of the Institute for Medical Research, Kuala Lumpur; 70 patients were thoroughly studied. The results, as stated in tabular form, are decidedly in favour of quinidine.

The average number of doses before absence of trophozoites was

Benign tertian ..	Quinine 4.5 (6 cases)	Quinidine 3.4 (10 cases)
Sub-tertian ..	" 6.6 (13 ")	" 4.3 (12 ")
Mixed tertian ..	" 9.6 (5 ")	" 4.0 (3 ")
Quartan ..	" 8.7 (10 ")	" 9.1 (11 ")

Dr. Fletcher reports that the temperature was not above normal after the 3rd day in the 34 men of the quinine group except in 5, in whom slight rises were seen up to the 5th day.

The results were "even better" in the 36 men of the quinidine group, the temperature not going above normal after the 3rd day except in three quartan cases in which trifling rises were noticed up to the 5th day. The results of treatment with quinidine were regarded by Dr. Fletcher as being "a little better" than those with quinine. No toxic effect of any consequence was noticed in the use of either drug. The response to Mayer's urine test was more constant and marked in the quinidine group than in the quinine group. The average dose of quinidine was 5 grains against 4½ grains of quinine, the difference being due to the fact that the average weight of the quinine patients was half a kilogramme less than that of the quinidine patients.

Dr. Fletcher suggests that the proper dose of quinine does not necessarily vary directly with the body weight, and he appears to imply that quinine was not tested under such favourable conditions as quinidine. Probably this belief accounts for the faintness of the praise which Dr. Fletcher gives to quinidine in his conclusion—that "the immediate effect of quinidine bisulphate in malaria is as good as, or slightly better than, that of quinine bisulphate."

The only really damaging evidence against quinidine is given by its own sponsor Major Acton, who reports several instances of cardiac depression following the use of the drug in ill-nourished patients and two cases of death which might have been caused by its use. The note by the committee on this subject is, "it seems clear that the effect of quinidine on the heart may constitute a real drawback to its employment." The committee find that the reports provide no evidence in favour of Acton's suggestion that the curative actions of these alkaloids are specially different for the different kinds of malarial parasites, and suggests that Acton's own evidence was susceptible of alternative interpretations. Another finding is that quinidine has been shown to have a real value in the treatment of malaria, but "it does not seem probable that the demonstration of its value would, by itself, have a very important practical effect on planting policy". "The addition of the quinidine yield to the quinine yield would somewhat increase the supply of such alkaloids, but probably not to such an extent as to make a big change in the cost of production". The committee suggest that the depressant action of quinidine on the heart muscle may be found to impose a limit on its use as an anti-malarial remedy. The enquiry has had one important result, to depose quinine from the place assigned to it by tradition and usage as the only valuable cinchona alkaloid.

Cinchonidine has been shown by Acton to be of equal value with quinidine; and cinchonine, though ruled out because of its toxicity, may prove to be of value if carefully purified.

The committee are "conscious of the fact that the contribution which they have been able to make to this important question is a small one." The enquiry may not have yielded conclusive results, but it has served to make it clear that further work remains to be done on the cinchona alkaloids. It cannot even be asserted that the findings disprove Acton's contention that quinidine yields a greater proportion of final cures in benign tertian malaria than quinine, and even if it were to be proved that quinidine was specially valuable only in cases which had relapsed after quinine and not in malaria generally, the drug might still be a valuable addition to our weapons of attack in relapsing cases.

The problems which have still to be solved are

(1) What are the special advantages and disadvantages of each of the alkaloids of cinchona against the different malarial parasites in various conditions such as chronicity, previous treatment, etc.?

(2) How can the greatest use be made of existing sources of supply of cinchona bark so as to produce the maximum of effect on malaria?

(3) What should be the planting policy of

India with a view to obtaining the greatest and most effective supply of alkaloids for the future?

We believe that these three questions cannot be answered at the present time in such a way as to command general acceptance. It is of great importance that they should be answered in an authoritative manner; it is not merely medical research workers who are concerned; the chemists, the forestry experts, and the higher executive officers of Government are also interested parties. The health and even the lives of millions of peoples are at stake and it is to be hoped that an enquiry will be instituted which will result in effective action being taken.

Meantime there is no reason for loss of confidence in our existing drugs, in quinine we have an old and tried remedy which, if properly used, continues to give results unequalled by any other drug in the pharmacopœia; "cinchona alkaloid," though a substance of varying composition, has the enormous advantage of cheapness. If it were standardised so as to be reasonably constant in composition and satisfactory in action, it is likely to be very valuable because of its abundance and low cost.

Colonel Gage's contribution to the problem to which reference was made in the last number of the *Gazette* is of great value. In it he refers to the enquiry into the cinchona alkaloids which was made by the Madras Government so long ago as 1886-87. After a test of the alkaloids on about 2,600 patients it was found that sulphate of quinine and sulphate of quinidine were equally effective, sulphate of cinchonidine was nearly as good, and sulphate of cinchonine, though somewhat inferior, was of considerable value. Colonel Gage advocates the use of the combined alkaloids when economy is important.

We hear that the Government of India is making an enquiry into the question of the use of the alkaloids and that Major Sinton is carrying out further investigations at Kasauli, under the same favourable conditions as were available to Major Acton in his Dagshai experiments. It is by an examination of the work which has been done in the past and by supplementing this where necessary by controlled experiments that information will become available on which a sound policy for the future can be based.

Meantime we appear to be swinging back to the position which was arrived at sixty years ago in Madras and it is hard to see how any great improvement can be made on the policy of those days, viz., to make use of all the alkaloids which are of proved value and let none of them be wasted. Even the least effective of the cinchona alkaloids is far more potent against the malarial parasite than the best of the vaunted substitutes.

OBSTETRICS AND GYNÆCOLOGY. A REVIEW OF RECENT ADVANCES.*

By V. B. GREEN-ARMYTAGE, M.D., M.R.C.P. (Lond.),
MAJOR, I.M.S.,

*Second Professor of Obstetrics and Gynæcology,
Medical College, Calcutta, and Second Surgeon
to the Eden Hospital.*

THE first quarter of the century has now passed and there are still many conditions in obstetrics and gynæcology, the ætiology or the treatment of which are matters of controversy. However, during recent years the great advances in biochemistry together with the team work of the larger clinics have made clear many problems and have dictated such direct lines of treatment as have a scientific basis.

OBSTETRICS.

Ante-natal care in its fullest meaning is the outstanding feature of recent years, for every hospital or clinic aims at maintaining a properly organised social welfare and clinical outpatient department. The result has been in many clinics that eclampsia has disappeared. Moreover the fetal and maternal mortality has been very greatly reduced thereby.

More and more importance is being attached to the proper feeding of the expectant mother, both as regards the avoidance of toxæmia and the preservation of the health of the fetus in utero. The diet advised is the avoidance of fats and red meat and the taking of a very much larger preponderance of vegetables and fresh fruit, the idea being to maintain the calcium index and give the fullest vitamin content; for it is now well recognised that the toxæmias of the early and later months of pregnancy are in a very large measure due to:—

1. A glycogenic disturbance in the maternal liver which expresses itself in the urine by the presence of ketone bodies, and is the origin of the fatty degenerated liver found at autopsy.

2. The intestinal intoxication factor which is so frequently associated with an unduly excitable sympathetic nervous system. The diet suggested for pregnancy cases in India is as follows:—

Cereals.—Oatmeal porridge or any of the breakfast foods, with milk. Brown or whole-meal bread, toast, rusks, cream crackers, biscuits.

Vegetables.—Any vegetable in any form except fried.

Fruits.—Any fruit either fresh or stewed.

Meat.—Beef, lamb, mutton, veal, not at all or only very occasionally. Pork never. Curry never.

Chicken (avoid duck, goose, game).

Any fish except salmon, mackerel, hilsa.

Eggs.

Croquettes or rissoles if not fried in deep fat.

Soups.—Any soup, thick or clear, but free from fat.

Sweets.—Any jam or jelly, marmalade or honey, but pure honey is best of all.

Milk puddings. Boiled puddings occasionally.

No pastry, no cakes.

Salads.—Any salad, but sparingly of salad dressing.

Fluids.—Water, aerated water, home-made lemonade, orangeade, weak tea, coffee, milk if desired.

No alcohol of any kind.

Butter may be taken if desired, but not in large amounts.

* Note.—In response to our request for assistance in preparing a review of the Indian medical year, 1925, these notes were received from Major Green-Armytage. They form so complete a separate review, however, that we publish the whole as a special article. Major Green-Armytage has recently returned to India after a tour of the principal clinics in England, America and the Continent.—EDITOR, I. M. G.

Cream, fat meats, and any fish fried in deep fat, should be avoided.

Fruits and vegetables must be taken at least twice a day, and meat if at all not more than once every other day.

Mild cheese such as St. Ivel is permissible.

Great stress is laid on the full examination of a primipara after the stoppage of two consecutive periods. If the uterus is retroverted, a simple and useful means of replacing it is to place the patient in bed with the foot of the bed raised and insert a small empty sausage-shaped penny balloon into the rectum and inflate it. The pressure thereof was successful in 18 consecutive cases within six hours thus doing away with troublesome manipulations, possibly under chloroform.

Hyperemesis Gravidarum.—Titus and Givens in America and Professor Watson of Edinburgh, have published very instructive papers on this subject.

The treatment advocated in severe cases consists in:—

(1) The use of carbohydrates to correct the lack of maternal hepatic glycogen.

(2) Rest in bed with sedatives.

(3) Keeping bowels moved daily.

(4) The administration of not less than 3 pints of water per day by mouth and also giving glucose and saline by rectum or vein in order to combat the dehydration factor.

It is imperative that a careful chart should be kept of the fluid intake per day; and this is controlled by accurately measuring the quantity of urine passed per day. The presence of albumen, or a continuously high specific gravity, or a diminishing volume of urine, or an increasing acetone reaction, after 4 or 5 days efficient treatment is looked upon as a matter of grave import demanding, may be urgent, termination of the pregnancy.

The treatment of mild cases is in a large measure a matter of dietetics as described in the Watson diet scheme above but for severe cases perhaps it would be as well to give the detail used by the writer in this country on the above principles. The patient is put to bed in a darkened room with cotton-wool in her ears. A competent nurse is in charge and relatives are kept away. Great care is taken, to keep the mouth and teeth clean and a glycothymoline or permanganate mouthwash is used constantly. A simple enema is given each morning and a rectal saline 9 ounces, glucose 1 ounce is run in slowly t.d.s. At 8 p.m. 15 to 25 grains of veronal in 1 ounce of pure olive oil is given per rectum and the patient sleeps all night. For the first 24 or 35 hours only fruit juice and bicarbonate soda water is given by mouth in frequent sips, if possible up to 60 ounces. A chart of total intake is kept and the daily urine measured and tested daily. As progress occurs more orange juice is given and then clear fresh vegetable or potato soup. Cream cracker biscuits and honey are allowed. Day by day the carbohydrate food allowance is increased until the more liberal dietary, enumerated above is possible, with the addition of skimmed milk, weak milk tea or milk jelly. Progress is oftentimes slow but the total intake of fluids and the total output and analysis of the urine are of the greatest importance. The writer has found as a rule that the veronal per rectum has to be given for a week and then if insomnia is still a worry, that bromides can be substituted or codeine grain $\frac{1}{2}$ given under the skin.

In very severe cases the writer has on several occasions given saline one pint pure glucose 5 drachms into the vein as recommended by Miss Farrar of the Mayo clinic. Pure anhydrous glucose must be used, or rigors may occur.

All cases of hyperemesis do not react to the above method, some cases go steadily down hill despite every effort. The greatest difficulty is to decide when to interfere in these cases. The above rules and data will be successful in 90 per cent of cases but if there is the slightest jaundice, or continued pyrexia, or urinary indication as above, or a peculiar mental muzziness difficult to analyse or describe, the writer would advocate not waiting or delaying till too late for oftentimes these patients sink

into fatal coma before or after delayed therapeutic abortion,—a tragedy and grief to all concerned.

Malaria.

Malaria during pregnancy is a condition which is often mistreated, but it is well to remember that malaria is a potent source of abortion and death of the foetus. Because of these facts only 25 per cent of women go to full term. Therefore malaria during pregnancy should be intensively treated; if this is done death of the foetus or abortions are rare. Practitioners should remember that the common causes of fever during pregnancy are:—

1. A *Bacillus coli* infection.
2. The death of the foetus.
3. A blood infection.
4. Intestinal parasites.

Therefore in every case the urine, the blood and stools should be examined. If conditions in India do not permit of such exhaustive methods, then before giving any quinine the patient should be saturated for 64 hours with 4-hourly doses of:—

Bicarbonate of soda	1 drachm
Potassium citrate	1 drachm
In water.			

The advantages of this are:—

1. It inhibits the growth of *B. coli* and possibly diminishes the fever.
2. It enables one to give quinine in lesser doses, e.g. 5 grains three times a day continuously, for quinine in an alkaline plasma acts far more efficiently.

Pernicious or hæmolytic anemia of pregnancy is one of the worst complications possible in India or in England. Many theories have been advanced to explain it, many methods tried to arrest or cure it, but the fact remains that in the majority of cases neither the pathologist nor biochemist has been of any assistance. The writer has records of over 100 cases seen too late, where no known examination of blood, urine or stool was omitted and yet nothing to elucidate the problem was ever forthcoming. In over 80 per cent of cases it was a fatal condition and he was of the opinion that the infarcts so frequently found in the placenta were the cause of this idiopathic anemia. Only early recognition can save these cases but this depends on a well organised and popular ante-natal scheme throughout all big towns and villages; for if in spite of dietetic, hygienic and drug treatment the course of the disease is progressive, the only procedure is to terminate pregnancy, but the difficulty is to choose the best method, for the shock of normal labour, with or without hæmorrhage, frequently kills these patients. The best method would appear to be the direct application of x-rays to the ovum, or foetus, or ovaries. The result is death of the foetus and consequent thrombosis of the utero-placental sinuses; the foetus then acts as a foreign body, and is, as a rule, expelled within 10 days without shock or hæmorrhage, but should natural labour not occur, it can be started and terminated successfully. It is probable that blood transfusion would be most helpful, but this method in India is hedged round by caste or prejudice.

Co-operative research on the whole subject of the anemias of pregnancy is urgently needed. The writer's opinion is that the condition is probably due to some endocrinous disease secondary to intestinal toxæmia, *vide* the recent fine work of McCarrison on nutritional disease. Moreover, it must be borne in mind that the clinical pictures of pregnancy *tetany* and pregnancy anemia are extraordinarily alike, and that in each, the patient has an *alkalosis* and a diminished blood calcium index, associated with or presumably the result of *hypothyroidism* and *hypoparathyroid* secretion.

It would seem therefore that research should be along the lines so brilliantly illuminated by McCarrison and Mellanby,—the clinician and laboratory worker striving hand in hand to elucidate and eventually prevent this disease.

Hepatic and Renal Toxæmia.

There is no condition that gives more anxiety. From time to time, within the last few years certain tests have

been boomed or put forward as the *ultima thule* as to whether a patient was in or out of danger, but alas! time and experience have shown their futility. In America, England and Germany many clinics set no reliance on blood or urine chemistry, and in India experience has led one to adopt the same attitude. For instance the ammonia coefficient is no certain guide, for in cases of moderate severity one may get the highest readings, and in fatal cases readings may be quite low.

Moreover all hepatic function tests have proved equally unreliable. Therefore the clinician has to fall back on older proved methods of examination such as proper measurements and analysis of the urine, blood pressure readings and ophthalmoscopy.

Some authorities believe that we have in the Rosenthal test, combined with consecutive readings of the urea concentration factor, a sounder means for determining therapeutic abortion.

The Stroganoff conservative method of treating *eclampsia* is now almost universal, and certainly the mortality is astounding, being under 10 per cent in his hands, but it must be remembered that in India frequently one does not see cases until very late, therefore in this country it is possible that Cæsarean section will always hold its place, for the most definite indication for Cæsarean section is anuria complicated by repeated fits, even though pelvic conditions are normal.

In connection with *albuminuria* it is most important to realise that we are not justified in assuming that those who have suffered from eclampsia or pre-eclamptic toxæmia may face future pregnancy without fear of any complications, for the writer has observed that the length of time toxæmic symptoms have persisted seems to be a factor in determining the occurrence of permanent renal damage. This observation seems of interest in relation to the management of such patients, either in private practice or in hospital, for such cases are frequently kept in bed and on an eliminative diet for many weeks,—thereby running the risk of permanent renal injury—a very serious matter—for later one may find that the patient is left post-partum with a "leaky kidney." The Johns Hopkins Hospital records show that chronic nephritis follows pre-eclamptic toxæmia in 60 per cent of cases. My own practice therefore is to advise termination of the pregnancy if organic renal change is demonstrated to have lasted, despite treatment, for more than three weeks.

Induction of Therapeutic Abortion.

During the first ten weeks the usual methods till recently have been advocated, but for such conditions as tuberculosis, heart disease and hyperemesis gravidarum vaginal hysterotomy is by far the most successful, for the method is rapid, certain and accompanied by no shock. After the tenth week until the twentieth the choice should be abdominal or vaginal hysterotomy, for by either of these means one can quickly and certainly empty the uterus. After the thirtieth week the cervix is usually soft, therefore the simpler and older methods are probably efficient. It might be as well in this connection to note that during recent years many reports have been published of *chloroform poisoning* following long anaesthesia with this drug during normal and abnormal labour or induction, therefore morphia and scopolamine together with open ether or gas and oxygen should be used if spinal anaesthesia is not possible.

Post-Maturity.

Both in private and hospital practice post-maturity is still far too frequently the cause of disaster to either mother or child. It cannot be too strongly insisted upon that practitioners and nurses should realise that 50 per cent. of post-mature children are born dead, die *in utero*, or are injured, who are born seven days or more after the full expected term. Only intelligent co-operation between the mother, nurse and doctor can reduce the frequency of these disasters for the evidence against permitting post-maturity is overwhelming. The methods

of induction are many. Some prefer the castor-oil-quinine technique which is as follows:—

- At 6-30 a.m., castor oil.
- At 7 " hot tea.
- At 7-30 " hot bath.
- At 8 " very hot vaginal douche.
- At 8-30 " hot enema.
- At 9 " 10 grs. of quinine.
- At 11 " 10 grs. of quinine.
- At 1 p.m., 10 grs. of quinine.

This method has its firm advocates, but is not invariably successful and may have to be repeated 48 hours later.

Others prefer the pituitary technique. Half a c.c. of pituitrin is given intra-muscularly every half hour until pains begin. This method the writer found very popular in Canada.

Some use the penny-balloon method of Lawrie, others the stomach tube means of Fitzgibbon, or Taylor's bag.

Some prefer the bougie method of Krause. If bougies are not available a very excellent substitute can be made by pushing a piece of thin bamboo down the ordinary tubing of a stethoscope, the tubing is elongated and a piece of silk tied at each end as in the figure.

Before induction it is imperative that the practitioner should see that the relation of the foetal head to the pelvis is normal, for if the head overlaps, the death of the mother may occur if it is a contracted pelvis.

One of the greatest dangers of inducing labour and

The New-born Baby.—Louise McIlroy has demonstrated, and her work has been confirmed by many other observers since, that the new-born baby after a long hard labour, especially if forceps have been applied, suffers from shock, and this shock is responsible for the pallor and general respiratory and cardiac asthenia. She advocates that the "shocked infant" should not be violently subjected to artificial respiration but after the mucus has been sucked out of the larynx should be kept absolutely quiet and as warm as possible. Such treatment or negation of treatment demands very great courage and fortitude on the part of the accoucheur, but there are few expert midwives or obstetricians who have not seen a foetus apparently lifeless put aside whilst urgent attention was given to the mother, and only later have found much to their surprise that the baby has recovered and is breathing normally. Possibly the success of the injections of strychnine and brandy or adrenalin which are frequently given to these children has its explanation in combating shock at the same time as raising the blood pressure.

Browne of Edinburgh draws attention to the frequency of neo-natal catarrhal pneumonia as the cause of death. In all probability this pneumonia is secondary to the passage of liquor amnii into the bronchi. This condition is very difficult to diagnose on a physical examination of the lungs but can always be demonstrated post-mortem. Suspicion however should be aroused if rust-coloured froth is seen at the mouth of the recently born baby. Intracranial injury or hæmorrhage can usually be certainly diagnosed by the syndrome of signs:—

- (a) Inability to suck.
- (b) Rigidity of the neck.
- (c) Cyanosis.
- (d) Twitching of the face or other muscles.

The onset of this syndrome is usually within 24 hours of birth and the prognosis is extremely grave. Repeated lumbar puncture has recently been strongly advocated, but the writer's experience does not favour optimism.

Version.

Dr. Potter of Buffalo has been severely stigmatised for turning and delivering all cases possible by the breech. But in all fairness, one must admit that he has taught the obstetric world one very valuable lesson and that is the technique of "ironing the vagina." The writer watched him doing this on several occasions and there is no question that this should be done by all obstetricians if the perineum is tight or tough, before the application of forceps in a primipara, or the delivery of a breech case. It is done under chloroform using ether soap plentifully and the gloved hand. First two fingers are put in the vagina and then the posterior and lateral margins of the canal are ironed out, that is the sphincter is stretched, then three fingers, then four and then the whole hand is introduced working backwards and forwards with the soap until the mucous membrane, sphincter vaginae, and levator ani are ironed out, that is completely stretched, flattened and dilated and the outlet patulous. The whole manoeuvre takes 10 to 15 minutes. By such means no rupture is likely and the writer saw him deliver a 10-lb. breech baby from a primipara without any laceration or trouble.

Version used to be advocated for minor pelvic contractions when the foetus was not large, but to-day version is rarely done except there be hæmorrhage, for whereas in a vertex presentation Nature slowly moulds the foetal skull, after version the moulding of a normally sized foetal head has to take place in the course of a few minutes, with the often consequent result of paralyses or cerebral injuries.

The practitioner in India is frequently faced with the urgent problem of dealing with hæmorrhage from

Bougie made of indiarubber tubing and bamboo.

certainly one of the greatest bugbears of the obstetrician is *premature rupture of the membranes*. This spells a long dry labour and danger to the child and mother, for as a rule, it indicates that the head of the child is not flexed, and in 50 per cent of primiparae it spells a posterior position.

Cæsarean Section.—Cæsarean section is one of the operations of emergency, and in this country it is an operation which every hospital staff should be capable of tackling because of the frequency of its indications. It must be remembered that the dictum "once a Cæsarean section always a Cæsarean section" is no longer tenable, for if the uterine incision has been correctly sutured with silkworm gut and catgut the scar will not jeopardise a future pregnancy *per vias naturales*. In India, unfortunately, it is the rule rather than the exception for patients to be seen or brought to hospital after the membranes have ruptured, but if the foetus is alive, the *low cervical operation of De Lee* renders it possible to deliver the mother with safety. For instance, Hirst in America has published 107 such operations after the membranes have ruptured, sometimes for days and after repeated examinations have been made, with only two maternal deaths. De Lee reports 136 with seven deaths. Such statistics cannot fail to impress surgeons in India. The operative technique is not difficult and can be very clearly followed in the beautifully illustrated article in the last edition of De Lee's book. The writer's experience is in complete agreement. The only disadvantage is that it takes more time. But in future operations the writer proposes to adopt the semilunar incision through the lower uterine segment with its convexity downwards which is advocated by Dr. Hendry of Glasgow, for the danger of hæmorrhage or risk of injuring the bladder are less therewith.*

* Since writing the above an opportunity of doing this has occurred with complete success, in just such a case as reported by Hirst. Mother and child living and well.

the uterus in the last few weeks of pregnancy. Frequently he has inadequate assistance, therefore the writer offers the suggestion that he should remember the letters D, 5 Ps and 3 Bs which stand for briefly:—*Douche*, *pituitrin*, *perforate the membranes*, *plug tight*, and *put on a pressure pad*. Apply a tight binder, keep the bowels and bladder empty. After 12 hours do podalic version, bring down a leg and leave to Nature to deliver slowly. *Faute de mieux*, this mnemonic is as equally applicable to hæmorrhage from a normally situated placental site as from a low implanted placenta.

Delay in the first stage, due to premature rupture of the membranes or *spasmodic or rigid cervix*, is one of the most frequent causes of distress and danger.

Dr. Polak of Brooklyn teaches that, where there is no abnormality in the size of the pelvis or child, one should:—

(a) Try the effect of the injection of a quarter of a grain of morphia and grain 1/200th scopolamine. Give hot vaginal douches every two hours and take care that the bladder and rectum are kept empty.

If this fails he advises that the whole vaginal vault cervix, and vagina, should be packed with gauze soaked in boroglycerine. The cervix then becomes soft, and after the rest ensured by an injection, labour proceeds normally and successfully.

Should there be any disparity between the foetal head and the pelvic inlet or outlet, the low cervical extra-peritoneal Cæsarean section should be done. In connection with premature rupture of the membranes, practitioners should remember that if the liquor amnii becomes a saffron colour or stained with meconium, or the foetal heart beats drop to 110 that the life of the child is in imminent danger. Therefore if the cervix is fully dilated and the maximum circumference of the child's head has passed through it, forceps delivery is imperative. Slowing of the foetal heart-rate is of far worse omen than rapidity. Therefore use De Lee's head stethoscope.

If the cervix is not fully dilated nothing should be done, though if the baby is dead perforation of the cranium is the best course to save undue distress and damage of the soft parts. *Hæmorrhage without pain* during the early months of pregnancy is a fruitful source of alarm. But it must be remembered that more than 25 per cent of women in the tropics "lose" a little or much during the first 13 weeks at that time each month when they would have been normally menstruating. Therefore such cases are not cases of threatened abortion and need cause no despondency; rest in bed is all that is needed. However, in this connection it may not be out of place to state that 75 per cent. of abortions occur at or about the time that normal menstruation should occur. But in these cases there is *pain plus hæmorrhage*.

Therefore it behoves the practitioner to warn every pregnant woman that although she may take normal exercise short of fatigue such as golf, tennis, dancing, swimming, etc., during the first five months, she should entirely refrain from all vigorous exercise, including coitus, during "the nine danger days" each month, which are the three days before, during and after that period each month which she would have been menstruating, if not pregnant.

The death of the fetus before and immediately after birth has been more and more the subject of recent research. Holland in London and Browne in Edinburgh have done a great deal of work in this connection, and it is now clear that intracranial hæmorrhage or tearing of the tentorium is the cause of death in 80 per cent of difficult labours, and that hæmorrhage into the spinal cord subsequent to injury is the commonest cause of death in breech presentations. For this reason all authorities particularly urge that every pregnant woman shall be seen in the 36th or 37th week with a view to discovering whether the child is vertex or breech, and urge that if it is breech it should be at once turned.

The relation of the foetal head to the pelvis is of immense importance.

If such examinations as the Munro Kerr or Muller manoeuvre were properly made at the 37th week and if at the same time the urine was systematically examined in all pregnant patients, childbirth disasters would become rare.

At this point we must consider the Kielland forceps, for without a doubt this new forceps is one for all specialists and teachers to acquire knowledge of. The writer found it being used in a large number of the American and Continental clinics. Its greatest advantage is that it accurately fits the head and therefore is of peculiar importance for posterior positions and for transverse lies of the head. The difficulties of learning the use of the Kielland forceps are few, but the obstetrician must be capable of exact judgment as to the lie of the fœtus. Posterior positions in primiparæ are bugbears of all obstetricians, therefore the writer is of the opinion that Kielland's forceps offer very distinct advantages, but they are not forceps for the general practitioner.

Thymic Hyperplasia.—Recently the writer had the privilege of visiting the State University Clinic of Michigan and was able to see the very excellent team work of Peterson and Miller. These two obstetricians have amply demonstrated that enlargement of the thymus, sufficiently great to give rise to grave symptoms such as inspiratory stridor (thymic asthma), cyanosis, dyspnoea, convulsions and even death was far more common than generally supposed.

They have shown that:—

(1) Thymic hyperplasia more frequently occurs in the male children of elderly multiparæ, who have had ante-natal complications.

(2) That radiography is the only sure means of diagnosis of such hyperplasia.

(3) That it is essential that every baby with thymic symptoms should be immediately treated by Röntgen rays lest fatality occur.

(4) That although 30 per cent of new-born children have an enlarged thymus, many show no symptoms, but others develop the classical symptoms later in infancy or childhood, which may prove fatal.

(5) That it is impossible to tell which infants with abnormally enlarged thymus glands are going to suffer from dangerous symptoms. Therefore it is only by routine treatment of all such cases by x-rays that dangers can be obliterated.

Now that the clinical picture is clear, the writer is sure that many clinicians will, like himself, recall cases to mind where, summoned urgently to a case of stridor, early convulsions, cyanosis, or so-called broncho-pneumonia in a normally born infant, accurate diagnosis was negative and all treatment unavailing. But now out of our darkness and impotence cometh forth light, for in future we have in roentgenography a sure means of routine diagnosis and therapy and one more application of preventive medicine.

The writer has seen three cases diagnosed and treated successfully by x-rays since he learned of this method.

Indigestion or diarrhœa in the breast-fed infant is frequently the reason given for taking a child off the breast. Nothing is more foolish, nothing often more disastrous. In 70 per cent of cases excess of sugar or fat in the mother's milk is the cause. In 25 per cent of cases it is the protein in excess.

Therefore in such a case do not give medicines, but (1) keep the nipples of the mother and mouth of the infant clean; (2) feed at both breasts for 7 minutes three-hourly, and before each breast feed, give 1 oz. of boiled water in which 5 grains of bicarbonate of soda have been dissolved; (3) give water between the feeds with a quarter level teaspoonful each of bicarbonate of soda and salt to the pint, dissolved therein; (4) weigh the baby regularly before and after each breast feed for a few days, and check on a chart the gain in weight per feed. If it is getting too little at a feed, supplement that feed with whey or skimmed milk. If too much, lessen the time at the breast; (5) the mother should avoid worry and constipation. Take ordinary diet but more fresh

vegetables, fresh fruit and salads than hitherto. She should *not* take in excess milk, sago and all those things beloved of nurses which cause abdominal distension and constipation, such as cotton seed, large quantities of milk, stout, rump steaks and curry; (6) each breast should be hot and cold sponged for a quarter of an hour twice daily and gently massaged from the periphery to the nipple; and (7) she should rest on her bed from 12 noon to 3 p.m. and remember that breast feeding is Nature's provision, that next best to this is cow's milk, whereas proprietary foods spell a whole gamut of ills, immediate and remote, such as acute gastro-enteritis, spasmophilia, rickets, chronic gastro-intestinal catarrh and glandular complaints, which may haunt the child all its life.

Röntgenography.

It may be said here that x-rays are being used more and more to facilitate the accurate diagnosis of abdominal tumours, especially pelvic ones where there is suspicion of pregnancy or a dermoid.

For conditions as to the size and lie of the foetus it is also very useful in those patients with large abdomens, for the radiograph may determine the necessity for Cæsarean section, induction, or version, or presence of twins.

The pelvic canal can be beautifully shown but unless the radiogram is stereoscopic it is difficult to adjudge data conclusively. On several occasions the writer has been able to demonstrate *outlet contraction*, which is a condition of the greatest importance to discover early and one far more commonly disastrous than previously thought to be, and, according to Blair Bell, it is the most frequent cause of complete rupture of the perineum and cerebral injuries.

The Puerperium.

Puerperal sepsis has not lessened appreciably during the last 25 years. But it is to be hoped that with better ante-natal care and less middlesome midwifery on the part of doctors and nurses the statistics of the second quarter of the century will be greatly improved. It has been proved that coitus during the last three months of pregnancy is a fruitful cause of sepsis. Therefore it is to be hoped that doctors will not be shy of warning husbands against this in future. Rectal examinations instead of vaginal examinations have not lessened the frequency of sepsis.

It must be remembered that labour is a pathological process frequently associated with morbid lesions. Therefore every patient should be shaved. Moreover it must be borne in mind that the vagina normally contains pathogenic organisms and that the lochia are alkaline. Therefore if there are injuries to the genital canal these organisms can very readily thrive and should resistance be lowered, virulent sepsis, with possibly the *streptococcus hemolyticus* as cause, may be started.

Quadrupeds very rarely develop puerperal fever in spite of the filthy conditions of their accouchement. The reason for this freedom is that Nature has so arranged that the line of drainage from the uterus to the cervix and vaginal outlet shall be downwards and outwards. Therefore should we not copy quadrupeds and place our patients for at least ten hours in every 24 in the right or left Sims' position? Till recently it has been the custom to keep Europeans during the puerperium for many days on their backs. The result is that the lochia tend to collect, in the uterus which may drop back, or in the posterior cul-de-sac, where pathogenic organisms can thrive and produce fever, if there have been genital lesions, or germs introduced. But if the patient lies in the right or left Sims' position for 8 to 10 hours per day with the head of the bed raised fever does not occur so frequently after a long labour, because these discharges can drain out. In almost every American clinic nowadays patients are being placed as a routine after labour for so many hours in the right or left Sims'

position, and leg and abdominal muscle exercises are ordered, to promote drainage.

The writer has demonstrated that it is possible to make a diagnosis of the type of organism that is attacking the patient by closely watching the physical signs and symptoms. Such diagnosis has the advantage that it greatly facilitates prognosis and treatment.

For instance staphylococcal infections show themselves by a slow ladder-like rise of the temperature; a stinking discharge, with pain, tenderness and distention below the umbilicus.

Streptococcal infections show themselves by rigors of early onset, a very rapid pulse, great anæmia, diarrhoea, non-smelling lochia, pain and tenderness below the umbilicus, with often general tympanites of the abdomen.

Bacillus coli infections are usually late in onset, with slow pulse, clean tongue, non-anxious expression and general puffiness of the abdomen. The urine is acid and opalescent.

In a doubtful case bacteriological examination of the urine will frequently give the clue. It should be remembered that 75 per cent of puerperal fever patients recover. In India a sloughing cervix, vagina or perineum are the commonest causes of puerperal fever.

Dr. Gordon Luker has reduced the mortality of streptococcal puerperal fever from 60 per cent to 30 per cent by his technique, which consists of:—

(1) 30 c.c. of anti-streptococcal serum three days running.

(2) Intramuscular injections of 5 grains of quinine every other day.

(3) Placing the patient in Fowler's position and giving hot rectal and vaginal douches 4-hourly.

(4) Prescribing large doses of alkalies by the mouth 4-hourly together with stimulants.

Under no circumstances or for any condition of puerperal fever is an intra-uterine douche to be given. Perhaps in this connection it is as well to quote the dictum of Professor Watson of Edinburgh that if a piece of placenta is known to be retained inside the uterus and that piece is no bigger than a dry walnut it should be left alone. Ergot, pituitrin and vaginal douches will cause it to be extruded in the great majority of cases. But if the piece retained is bigger than a dry walnut then it should be removed under an anæsthetic with sponge-holding forceps, the fenestræ of which are covered with gauze. The finger or intra-uterine douche should never be used. The reason why any intra-uterine douche is always contra-indicated is because the pressure at the nozzle of such a douche is at least 7 lbs. to the square inch. Therefore such pressure may drive organisms on the surface into the deep uterine sinuses and set up rigors by dislodging septic emboli or protein particles. Moreover it must be recollected that the Fallopian tubes may be patent and therefore the germ-containing fluid may be carried into the general peritoneal cavity—this latter occurrence being particularly prone to occur up to the 6th month of pregnancy.

Parenthetically it may be here stated that for the latter reason, following the gynecological operation of *dilatation and curettage*, nowadays very few surgeons flush out the uterine canal, lest the fluid be carried through the tubes to the peritoneal cavity. The surgeon contents himself and safeguards his patient better by drying the cavity, swabbing with iodised phenol and putting in a gauze wick drain; for who can say what harm may not occur to the delicate ciliated tubal and fimbrial epithelium, to say nothing of the pelvic peritoneum from an alien fluid or possibly septic uterine cavity.

Retained Placenta.—In many instances this condition occurs owing to the nurse or doctor worrying or rubbing the uterus immediately after the expulsion of the child. Such treatment inhibits proper retraction of the uterus. In the absence of hæmorrhage the sole duty of the attendant is to control the fundus of the uterus and nothing else,—either with the hand or sausage-shaped sandbag.

Retained placenta is most common after a long and tedious labour where shock and exhaustion are present. It cannot be too urgently impressed upon attendants that if there is *no hæmorrhage* but there is exhaustion and shock, their first duty to the patient is to control the uterus and place the patient comfortably in bed, if need be giving a hypodermic of morphia to ensure recuperation, before attempting expression or manual removal of the placenta under chloroform.

Hundreds of deaths occur every year in India from non-observance of this rule. No other duty or social function should interfere with the proper observance of this rule, for if in a patient already exhausted a hand be introduced into the uterus to remove the placenta the shock will be multiplied by ten and a fatality occur.

During recent years there have been many publications recording fatalities and emphasising the importance of treating the shock, in the absence of hæmorrhage, before attempting manual removal of the placenta. The method of running a pint of saline into the umbilical vein of the cord is only successful in 25 per cent.

Osteomalacia.

During the past year some magnificent work has been done on this subject by Maxwell in Pekin. He has demonstrated the urgent necessity of early diagnosis in these cases and shown how frequently the condition occurs, and one's experience in India confirms this. Dr. Maxwell and his fellow-workers have proved incontrovertibly that osteomalacia is one of the deficiency diseases of pregnancy, and if these patients in the early stages, suffering from the symptoms of osteoporosis and softening of ligaments with the subsequent pains and aches, are treated with a full vitaminic A, B and C diet and are given calcium lactate and large doses of cod-liver oil over a long period, the symptoms subside and changes in the bones do not occur to an appreciable extent, *vide* writer's article pp. 53-55, in this number of *Gazette*.

The value of this work should be particularly applicable and known in India.

GYNÆCOLOGY.

Wilfred Shaw in London has carried the work of Hitschmann and Adler in 1908 a stage further on the subject of the relation of ovarian function to *menstruation*. It is now possible to state:—

(1) That the pre-menstrual changes are first observed about the 14th day of the cycle; the cycle being regarded as commencing on the first day of the menstrual discharge. At the end of the menstrual cycle, the pre-menstrual endometrium resembles the decidua of early pregnancy.

(2) That ovulation in the human female takes place between the 13th and 17th day of the cycle. This fact is of extraordinary interest to those who are cognizant of the Mosaic law, for most readers are aware that despite persecution, the Jews are the most prolific race in the world, but perhaps they are not aware that coitus amongst orthodox Jews may not occur before the seventh day following the *last* day of menstruation. Thus we find the Mosaic law empirically demanding that coitus should occur on or about the time of ovulation.

The writer has found as the result of observation over many years that the elective days for procreative coitus are the 7th, 9th and 11th days *after* the cessation of the menstrual discharge.

Sterility.

Sterility is a problem which has always been a difficult one to solve. It will help matters to divide the causes of sterility into four groups from the point of view of the woman, *viz.*:—

- (a) Developmental.
- (b) Congestive.
- (c) Infective.
- (d) Constitutional.

It is probable that at least one-quarter of sterile women owe their condition to developmental defects which in future generations may be prevented by making

the mother understand the dangers of overtaxing the nervous and physical powers of their daughters during puberty and early menstruation.

Moreover it is certain that the diet of the modern child from infancy to adolescence is responsible for many defects, for in this era of patent milks, tinned foods and badly cooked substances lacking essential vitamins there can be no question that the endocrine system of the young girl is starved often from birth of essential vitaminic stimulants. Hence the dictum:—

"The vitamins are to the endocrines, what the endocrines are to the economy."

Many cases of sterility of congestive origin are due to ignorance of or irregularities in marital habits. The practitioner should not burke enquiry into such intimate matters if he has the requisite knowledge to proffer.

In recent years the *Rubin insufflation test* has been of great aid in helping to discover the cause of sterility in some cases, and curing sterility in others. This test is extremely simple and the writer has used it in many scores of cases. It should be done on the 5th day following the cessation of menstruation, no anæsthetic should be given, great care should be taken that there is no sepsis in the cervix and that the pressure of CO₂ should not be allowed to register over 160 mm. of mercury. The writer uses Dr. Rubin's own apparatus but that of Dr. Provis is equally suitable. In a future paper the technique and results will be described. Experience has proved that 12 per cent of sterility cases can be cured by this test alone.

In this era of *birth control* a word of warning on the subject of contraceptives is necessary. It has been shown that if contraceptives are used by women for a consecutive period of three years after marriage, in only 10 per cent. does a future pregnancy occur. The explanation is that such abominations as quinine pessaries and cervical caps, etc., tend to cause an endocervicitis with destruction of the cilia. Moreover, in view of the recent work of Barnard and Gye on cancer it may here be pertinent to enquire whether the increase of cancer in women who have had only one or two children, may not be related to the frequency of endocervicitis accompanying old lacerations, and the use of contraceptives.

Here when mentioning endocervicitis the writer would like to introduce a word of protest against the common practice of painting *erosions of the cervix* with picric acid and other solutions. An erosion is the outward and visible sign of an inward and invisible endocervicitis. Therefore all such applications are utterly useless, for it should be realised that the cervix is the tonsil of the pelvis. And that whereas the erosion is visible, the endocervicitis with its crypts and hypertrophied racemose glands is the hidden cause of the leucorrhœa and pain in the back, anemia or joint pains and that no solution can penetrate or disinfect these glands or ovulate Nabothi, though possibly ionisation might do so. Hence severe erosions, or endocervicitis should be treated by the Bonney or Sturmdorft technique.

The sacral ache of erosions is due to enlarged glands in the hollow of the sacrum pressing on nerves.

It is not sufficiently known that 60 per cent of gynaecological lesions are due to and the direct result of poor obstetric practice. It therefore behoves us to urge that *every practitioner should attend a proper post-graduate gynaecological and obstetrical course* at least once in five years and that the teaching of this subject to the present and future generations of medical students should be based on anatomical and pathological lines. For instance a student often becomes qualified without in the least understanding the imperative importance of the pelvic floor and pelvic diaphragm. Too frequently is the teaching of obstetrics made a water-tight compartment separated from an equally water-tight gynaecological department. The teaching of these subjects should be by a live method so that students and post-graduates may visualise and memorise.

No gynaecological demonstration can be complete unless the teacher has multiple half-sections and dissections

of the female pelvis before the class. The writer's practice is to keep a dozen pelves removed at autopsy by amputating the thighs and dividing the vertebral column in the lumbar region. Some of these specimens are sagittally divided, and all of them are chosen at autopsy to illustrate morbid lesions, one and one only being normal. Teaching students and post-graduates in this way, they can examine and see all the important points. Moreover pelvic surgery becomes then a subject of ease and interest to elucidate.

Similarly, in teaching obstetrics, the live recently-born infant is placed in a large specially-constructed female dummy, the manœuvres and mechanisms of labour, together with every variety of presentation and lie can then be illustrated. Such demonstrations are live things and not dummy ones and thereby interest and intelligence are titillated.

Hæmorrhage from the non-pregnant uterus is the first and commonest sign of cancer, but, alas, in India it is the exception rather than the rule for patients to be seen sufficiently early to warrant Wertheim's operation—invariably it is the old story, hæmorrhage for months and no proper examination.

Only an intensive propaganda on the subject of cancer can do anything to lessen the incidence of this condition.

Radium has its advocates. In America, if the condition is operable, as a rule radium is first used and later operation done. But on the Continent and in England most surgeons, because of the disadvantages of radium, prefer when possible to operate first and later use radium.

It cannot be stated too strongly that radium only rarely has any curative effect, whereas surgery in early cases is successful in 60 per cent.

In many clinics a cervix which is lacerated, eroded and hypertrophied, is looked upon as potentially a pre-cancerous cervix. Therefore in all these cases a high amputation of the cervix or a vaginal hysterectomy is advised or done.

Chronic metritis is a condition peculiarly common to-day. Some suggest that it owes its origin in many cases to prolonged contraceptive methods, but all are agreed that it is a low grade infection of the uterus, in many cases subsequent to labour or abortion. It causes progressive anaemia from hæmorrhage and is frequently associated with general ill-health such as pyorrhœa and intestinal stasis. These are the cases which drift into hospitals all over the world after having been cured frequently by general practitioners or others. There are only two ways of treatment,—radium or hysterectomy. The more experienced the gynecologist, the more frequently does he prefer to remove this uterus *per vaginam*. The mortality and disability of vaginal hysterectomy for these cases in the writer's practice is 3 per cent.

Miles Phillips of Sheffield has recorded 300 cases with a mortality of 2.5 per cent for this operation.

Abdominal hysterectomy is of course much easier but has a greater mortality and disability rate.

Fibroids are even more common in India than in England. Victor Bonney has revived and popularised the operation of myomectomy in order to conserve the uterus. There is no question whatever that this is the ideal operation whenever possible and should be done. *Endometriomata* have a prominent place in the literature of the last few years, and are undoubtedly far more common than one supposed. They may occur anywhere in the pelvis, but are more frequent on the ovary and in the recto-vaginal space. These tumours can frequently be entirely removed, but sometimes disappear under radium. At operation small hæmorrhagic cysts or puckering of the peritoneum should enable the diagnosis to be suspected. Extirpation of the ovaries and uterus together with the tumour is the best method.

Prolapse, like the poor, is always with us. Indeed it has been stated by an eminent Indian obstetrician that 75 per cent of parous Indian women after the age

of 30 suffer from prolapse. The habits and type of labour in Indian women explain this.

It cannot be too strongly affirmed that should a patient with prolapse seek operative relief, the technique employed must be that of the Manchester School, that is to say prolapse to-day must be treated anatomically by the vaginal route. Too often in India do we still find women coming to hospital with the cervix, bladder or rectum bulging at the vaginal outlet, who narrate that they have had a ventro-fixation in some other hospital. Such surgery is unworthy and an anachronism, for prolapse is a hernia, and can only be treated as a hernia by a technique comprising amputation of the cervix with re-apposition and suturing of the pelvic fascia and levator ani in order to close the hole through which the hernia has appeared.

Stacey Wilson has brought to our notice that *slight uterine prolapse and vaginal laxity*, following difficult or normal parturition can be cured or palliated by *re-education of the muscles* constricting the vagina, so doing away with the necessity of temporary troublesome pessaries. He states that if the tone of the muscles which occlude the vagina in a case of slight prolapse or gaping vagina, after parturition, be tested with two fingers in the canal by asking the patient to contract the sphincter and the levator ani, by "tightening herself up" as if she were endeavouring to control a sudden attack of diarrhœa and one finds that the "grip" is practically nil, that re-establishment of full tonic contraction of these muscles is only a matter of time. The patient is therefore told to contract the muscles of the pelvic floor every hour of the day and to maintain the contraction as long as she can, for when she so to speak tightens the anus to prevent escape of diarrhœa she at the same time contracts and lifts the vaginal vault and outlet.

If these rules are carried out, as they easily can be, the muscles which diminish the lumen of the vagina will in a very few weeks greatly increase in vigour; so much so that they will be able to grasp a single finger with ease, and a continuance of the voluntary efforts will so re-establish the habit of tonic contraction that slightly prolapsed uterus or dropped pelvic diaphragm can be retained in place without any mechanical support.

Another practical point about these exercises, (if they are effectively carried out), is, that not only does the sphincter vaginae regain its tone but the walls of the vagina come to lie normally in apposition again, so curing that most distressful symptom of *ballooning of the vagina* with air or water so frequently complained of.

Retroversion of the uterus is a perpetual source of strife. One school urges operation in every case, another will not operate unless there are symptoms such as sterility, dyspareunia or associated prolapse. Between these two schools there is a golden mean, for although many patients with a retroverted uterus do not become pregnant, there is no doubt there are many who do conceive.

It is exactly in cases of retroverted uterus that the *Rubin insufflation test* is so valuable, for Rubin has shown incontestably that all such cases should first undergo this test. His contention, is after a thousand insufflations, that if the CO₂ passes with ease through the tubes and without undue pressure with the uterus still retroverted there is no indication for operation for sterility *per se*; but, if the CO₂ does not pass easily or only under excessive pressure or after first anteverting the uterus, it is to be presumed that there is a mechanical kink in the tubes. These are the cases for which Gilliam's operation is so gratifying in its results.

Such being the scientific aspect and explanation, it behoves all gynecologists to set their hearts against the glamour of doing an abdominal operation for which, unless this test has been done, there is no scientific justification.

Of course a retroverted uterus associated with prolapse of the uterus or prolapse of the ovaries, is entirely a different matter demanding different treatment.

Retroversion after the Puerperium.

It is very necessary to bring to the notice of all practitioners the universal teaching that every puerperal patient must be examined 15 to 21 days after confinement. From a very wide and long experience the writer is afraid that this rule is not observed in India as closely as it should be, with the consequence that prolapse, backache, and what some call the subinvolution uterus (chronic metritis) are very common.

If puerperal patients were treated from the beginning by placing them in the right or left Sims' position for 8 to 10 hours per day, retroversion would less frequently occur with its sequelae; for obviously a bulky, backward uterus tends to slide down the line of the vagina and project as a hernia, through the recently stretched and perhaps poorly involutioned pelvic diaphragm—giving rise to those symptoms of the "inside coming outside", so often complained of, when the patient stands or walks about after confinement.

In the majority of cases all that is necessary is to insert a ring pessary, after reposition of the uterus, for 6 to 8 weeks. But let it not be forgotten that prevention by early postural treatment is the best method.

Endocrinology.

It is recognised to-day that the strains and stresses of the human body are harmonised by two main agents—the central nervous system and the endocrine glands. This fact becomes all the more interesting in consideration of the recent work of Keene and Hewer, who have shown that the function of the pituitary, adrenals, thyroid, parathyroid and thymus are actively established between the 8th and 20th week of foetal life.

It is unnecessary to reiterate well-known facts, but the writer wishes to emphasize certain recent observations of Langdon Brown, Vines, Cushing, Moore, Williams, and Berman which have proved to be of diagnostic value.

For instance, *thyroid deficiency* may show itself by stunted growth, nocturnal enuresis, night terrors, relaxation of ligaments, delayed puberty, back-ache, orthostatic albuminuria or absence of the outer third of the eyebrow. Langdon Brown calls attention to the fact that tonsillar hypertrophy and sepsis are also frequently associated with hypothyroidism in children, and it would appear that this is to some extent due to defects such as a lack of iodine salts and vitamins in the diet.

The exhibition of parathyroid combined with thyroid gland is useful for those devastating symptoms of the menopause occasionally met with.

The pituitary gland like the thyroid hypertrophies during pregnancy; this accounts for the enlargement of the face and pelvis which so frequently occur. It is probable that the glycosuria of pregnancy has a similar explanation.

Pituitary insufficiency before puberty causes obesity, principally below the navel, non-development of the secondary sex characters and the *masculine type of pelvis in women*. After puberty it causes amenorrhœa. This form of amenorrhœa is best treated by intramuscular injections of pituitrin daily for three weeks, although Williams recommends 10 grains of the whole gland by the mouth three times a day. In connection with pituitary insufficiency, Cushing has observed a very curious trio of conditions viz.:-

- (1) Absence of the half-moons of the fingers.
- (2) Small black moles, (beauty spots), all over the body.
- (3) Spaced, under-developed or twisted upper lateral incisor teeth.

The writer has confirmed these observations on many occasions; such people are undersexed and obese below the waist line.

The ovarian hormone co-operates with the thyroid, parathyroid and pituitary glands. It is the ovarian hormone factory, including the corpus luteum, that is annihilated by x-rays.

In connection with the gonads, Williams quotes Virchow's dictum:—

"Woman is a pair of ovaries with a human being attached: whereas man is a human being furnished with a pair of testicles."

Although not strictly related to gynaecology, perhaps Scotch readers will be interested to learn of the research work of Dr. Moore of Chicago on the *testis*. He has shown that the normally descended testicle, when artificially replaced within the abdomen rapidly degenerates, but if it be rescued and put back into the scrotum it gradually recovers. He concludes therefore that temperature has something to do with the health of the normal testis, and that this is the explanation of that grotesque structure, the scrotum, viz., that it is a thermo-regulator to maintain the health of the seminiferous tubules. Williams therefore aptly asks if the over-clothing of the scrotal area which is so habitual in elderly men is not a powerful contributory factor in determining premature decline in sexual capacity. For verily the advantage of free ventilation of the scrotal area may be seen in the *bodily* and sexual vigor of those who wear kilts!

The *adrenal glands* are very closely related to the gonads and also to the vegetative nervous system, as is well known.

But recently it has been shown that if the cortex of the adrenals does not develop properly in the foetus, an anencephalic monster is born, showing that the adrenals have also a direct relationship with the central nervous system. *The adrenals are the organs of fight, flight and fright*, i.e., they are the organs of response to the emotion of fear. Individuals of the adrenal type are very hairy over the chest and body; often they are red-haired and have large canine teeth; often they are freckled, big boned and have a large sex appetite.

The adrenals are organs of peculiar interest to the sun-dried Anglo-Indian, for that the vigour of this combative gland rapidly declines with advancing years (and in this climate particularly) is a matter of common observation. Indeed one asks oneself did the great Francis Bacon foresee this research when he wrote in 1600 A.D.:-

"Men of Age Objecte too much, Consulte too long.

"Adventure too little, Reporte too soone, and seldome

"Drive Businesse home to the full period; But contente themselves with a Mediocrity of Successe."

Finally, it may be of interest to readers of a philosophic turn of mind that the first reference to the adrenal type of man one can find is in Genesis, chapter 25, for in the account of Rebecca's confinement it is written:—

"And when her time was come to be delivered, behold twins were found in her womb. He that came forth first was red and hairy like a (kid's) skin and his name was called Esau. Immediately the other coming forth, held his brother's foot in his hand, and therefore he was called Jacob. And when they were grown up, Esau became a skilful, cunning hunter and a man of the field, but Jacob a plain man and smooth, dwelt in tents."

Does not this ancient reference open up a grand vista of thought? Does it not, through the ages, foreshadow certain easily recognised racial characteristics of to-day dependent upon or due to endocrine differentiation and development?

"O day and night, but this is wondrous strange,

And therefore as a stranger give it welcome.

There are more things in Heaven and earth, Horatio, Than are dreamt of in your philosophy."

RETIRING.

By "I. M. S., retired."

WHEN bearing the full heat and burden of the Indian day many an I. M. S. man looks forward very longingly to the arrival of the day when he can afford to retire from his active service in India, and return to his misty northern island home.

There is many a civil surgeon whose day is full of work and responsibility in a trying climate; whose opportunities for leave are perhaps few, or who, may be, thinking he will bring the day of retirement nearer does not even take such opportunity of leave as is afforded him.

To such, hardly a day passes without his thinking of the day when he sees for the last time what someone has described as the best view in the East, Bombay harbour from the stern of a P. & O.

Yet when that time comes he will find life at Home full of new difficulties which he did not perhaps anticipate. Perhaps he has nothing to attach him to any particular part of the country, and the greater the choice the greater the difficulty. This happened to the writer who spent his first year wandering all over Great Britain, staying here and there, and never being able to decide, until finally in despair he went for a week-end to a place where he had a couple of old hospital friends; arriving on Saturday night, and buying a house he did not like on Monday morning.

No one will let you rent a house these days for fear of falling prices; prices are coming down, but you cannot judge by advertisements. A pre-war £1,000 house now fetches about £2,500.

It is quite likely that if the place is found that seems the one "beloved over all" there will either be no available house, or none that is suitable, and one has to be built. This has also happened to the writer. The price of building is falling; the firms who tendered £3,500 for a simple eleven-roomed house in 1921 re-tendered and built for £2,400 in 1923, in other words a simple building which cost about eighteen pence a cubic foot in 1921 fell to tenpence or one shilling by 1923, and still costs about the same price.

I remember we had very hazy ideas on how much it would cost to live at Home in reasonable comfort. The writer and his wife have found living in the country with two servants, a gardener, and a car, and no family, and no entertaining beyond friends to stay in the summer, costs about £100 a month tax free, or £1,500 per annum, to allow for holidays, income tax, etc.

Domestic servants are a difficulty; the old faithful servants we associate with the old home of our youth are no more. To get any in the country is difficult, and such may be reckoned to cost, in wages and food, £100 a year each. The writer advertised for a cook general for a month at £52 a year, and did not get a single reply. He put in one small advertisement in a nursing paper for a trained gentlewoman as nurse companion to a relative at £60, and got over 70 replies in three days. Such are conditions of service in England to-day.

Besides all this, with the present trade depression, there is the constant menace of industrial trouble; but one must not be misled either by the noisiness of a very small minority, nor by the national characteristic of everlasting self-depreciation. After all the old country is still the best place in the world to live in.

When the situation of the house has been decided on, the house found or built, the servants obtained, the furniture bought, and the boxes have been unpacked, the most difficult matter of all remains. *What to do?*

To anyone whose days have been full of work, interest, and responsibility; whose every action almost has affected the life of somebody; the pursuit of sport, pleasure and pastimes soon palls, and becomes stale, flat and unprofitable.

The I. M. S. man's career has unfitted him for general practice, nor did he retire with the object of spending his days in an occupation more than ever full of anxiety and worry, disturbed nights, and unpaid bills. Nor of course is the social position of the general practitioner in England that of the I. M. S. officer in India. There is nothing snobbish in the fact that looking back on one's service in India, one of the things one appreciates now more than anything is the fine class of European who manned the Indian Services, and formed

one's circle of friends. After retiring, few new ones are formed of the same class.

There is consulting work, but that again is open to very few; only to those I. M. S. men who have world-wide reputation only are the staffs of our big medical hospitals open—to the many, there is little chance in the consulting world against the young men who for years since they took high qualifications have been working, and working hard, and for nothing, to be in a position to apply hopefully for any such hospital appointment as may become vacant. To do consulting work without being on a hospital staff holds no prospect of any success.

There is however a branch of medicine very suitable for a retiring I. M. S. man, if he will only make himself conversant with it before he leaves India, viz., private or public sanatorium work; the former for choice.

But many men imagine that anyone can run a sanatorium, and do not even recognise that it is a branch of work requiring much special study, experience, and character, if the sanatorium is to be a success.

But an I. M. S. man with retirement in view could do much to prepare himself to take up such a post, for example by reading the proper literature, and by making himself conversant with x-ray work, especially x-ray chest work; and the technique of induction of artificial pneumothorax. This latter is being commonly used in all first-class sanatoria now, and the facilities for acquiring dexterity in it are much greater in a civil hospital in India than in either the general or special hospitals in England, where the I. M. S. man has no standing. He could supplement this by a short course at special hospitals on coming Home, and if put in the way of it by some one connected with the sanatorium world, could get an insight into the routine work. The writer has found much interest, happiness, and no small addition to his pension in this manner. Should any I. M. S. man with retirement in view think of taking up such work, the writer would be pleased to correspond with him, and could probably be of some assistance to him as the Editor has promised to forward any such letter to the writer.

Current Topics.

Proceedings of the Permanent Committee of the International Office of Public Health.

THE following is an abstract, translated from the proceedings of this Committee, prepared from materials kindly forwarded by the Public Health Commissioner with the Government of India, of the session April—May, 1925:—

The meeting was held at Paris from the 27th April to the 6th May, 1925, and was attended by delegates from 28 different countries and states, Lieutenant-Colonel J. D. Graham, C.I.E., I.M.S., Public Health Commissioner with the Government of India being present as delegate from the Government of India.

It was noted that no less than 13 states had signed their willingness to adhere to the suggestions put forward by a sub-committee for the provision of free diagnosis and treatment of venereal diseases among sailors of the mercantile marine services at different international ports. A circular with reference to the standardisation of anti-diphtheritic serum also received general assent. Further, 19 out of 37 states circularised had expressed their adherence to a proposed scheme for sanitation of maritime ports in different countries. The special report by the Council of Hygiene of the League of Nations with reference to the Opium Convention was also considered.

Subsequent to this, the present position with regard to certain epidemic diseases was considered:—

Anthrax.—On the suggestion of the Minister for Agriculture, Czecho-Slovakia, the proposition was considered as to the feasibility of the control of anthrax at the port of export of infected hides, rather than at the port of their entry. It was noted that, although this industrial disease has now become relatively rare, yet it cannot be altogether neglected; for instance, 873 cases with 126 deaths have been recorded in Great Britain during the past 15 years.

Scarlet Fever.—The replies to a general questionnaire sent out were considered. In Roumania, a country where the disease was formerly frequent and with a severe mortality, it had almost disappeared during the great war, and had since recurred only in attenuated type. Isolation of cases has proved the most valuable of general measures, having reduced the case mortality from 25 per cent. in 1898 to 6.9 per cent. in 1923. Bacteriological studies, especially in America and in Italy, had shewn that the problem of the ætiological agent was now presumably solved, but it was as yet too early to make a definite pronouncement.

Plague.—Reports were considered from Holland, Japan, Norway, and various British colonies. The British colonial report in general dwelt upon the necessity for systematic observations upon the geographical distribution of different rat species and the different geographical and seasonal distribution of their fleas. It is hoped that a detailed report may shortly be considered. In Tananarivo, Madagascar, *Mus alexandrinus* proved to be the prevalent species, and *Xenopsylla cheopis* the prevalent rat flea species. *Pulex irritans* was rare, but *Ctenocephalus canis* a flea frequently found in houses. In Europe generally, with the replacement in the 18th century of the black rat by the grey, plague had disappeared. *X. cheopis* is apparently the chief agent in the spread of plague throughout the world, especially when it is transported from port to port via ships harbouring infected fleas; but *Ceratophyllus fasciatus* is also of importance. *Ceratophyllus* tends to increase in numbers as *Xenopsylla* disappears, whilst the rôle of *Pulex irritans* is nearly negligible.

Cancer.—A special report on cancer incidence in Spain from 1900 to 1920 was considered. It was further noted that in Czecho-Slovakia a marked increase had been noted in the cancer incidence rate, especially among females. In 1919 the incidence of deaths from cancer was 45.2 per mille of deaths, in 1923 no less than 60.1 per mille.

A special enquiry into the percentage of operable cancers of the uterus in England, Italy and Holland had shewn that only some 10 per cent. of such cases gave favourable prospects of cure by radical operation. In Belgium a total cancer mortality of 50 per mille of deaths was probably correlated to a general increased average expectation of duration of life as the result of improved measures for public health.

Relapsing Fever.—A special report attributed much of the so-called relapsing fever in Persia to the malarial parasite, rather than to relapsing fever. The true rôle of *Argas persicus* as a transmitter remains to be elucidated.

Leprosy.—The leprosy incidence appeared to be declining; and, as with syphilis, most of the cases appeared to be under hospital control. In Norway the incidence had fallen from 2 per cent. of the population in 1852 to 1 per 20,000 of population in 1923. In Algiers only about 150 cases had been reported in 30 years; Jews were not affected; the indigenous inhabitants were almost exempt; but the chief incidence was amongst Europeans and especially Spaniards. A sum of some £30,000 had already been collected by the British Empire Leprosy Relief Association. In Indo-China a census in 1923 had shewn a total of 5,813 lepers, of whom 4,454 were already segregated in institutions. Here the practice of village segregation had proved especially useful, and was more readily tolerated than

isolation in asylums. In New Caledonia 1,168 lepers were reported, an incidence of 2.48 per cent. of the population, and village segregation was in vogue. Treatment by the ethyl esters was giving encouraging results, but a final opinion on this subject could not yet be given.

Kala-Azar.—The position was interesting. A special commission was working in Assam under the ægis of the Indian Research Fund Association on the transmission problem. (The information on this heading in Dr. Pottevin's minutes is inadequate. In addition to the commission in Assam, a whole-time chair in research work on this subject has been endowed for the past five years at the Calcutta School of Tropical Medicine by the Indian Tea Association; a further auxiliary enquiry at the same School has been in existence for the past two years—endowed by the Indian Research Fund Association; a special enquiry has been endowed by the Madras University; the Royal Society of London has now a special commission consisting of Dr. Hindle and Major W. C. Paton, I.M.S. (retd.), working in China; whilst the Public Health Committee of the League of Nations has recently appointed a special commission to investigate the problem as it occurs in Southern Europe and the Mediterranean area. If this—the most difficult current unsolved problem in tropical medicine—is not solved within the next year or two, it will not be for want of funds applied or of skilled investigators appointed to enquire into it).

Tabes and General Paralysis of the Insane.—Information as to incidence in different countries is still being collected. In Japan it is stated that treatment has of recent years so modified syphilis as a disease of the indigenous race that it is not at present possible to speak with certainty as to the incidence of tabes and of "G. P. I." In British India medical opinion appears to be almost unanimous that whereas such diseases are not uncommon among Europeans they are very rarely seen in Indians. In Germany, it would seem that, with increasing success of the treatment of visceral syphilis, neuro-syphilis appears to be on the increase. On the contrary the reports from England do not bear out such an idea.

Alastrim.—In 1924 in England and the low countries there were notified 3,797 cases of small-pox. They were of all mild type, and only 8 deaths were recorded; 10 only were confluent and 3 only hæmorrhagic,—these last 3 all proving fatal. Most of these cases occurred in non-vaccinated persons.

Does such evidence tend to shew that the virus of small-pox is, to-day, less virulent than formerly? A special report on this subject from Portugal was promised for the next session of the Committee.

Miscellaneous.—In Italy the general death-rate at 16.48 per mille of population was now similar to that prior to the years of the great war. A special Act for the betterment of public health, recently passed under the Mussolini regime, was perhaps the cause of this.

Special memoirs contributed dealt with an ethereal vaccine against rabies; the rôle of cholera-carriers in epidemic cholera in Japan and British India; yellow fever in West Africa; typhus in Japan; and practical insecticides. (It is obvious that the sphere of work and investigations concerned cover a large area and are of considerable importance in the field of tropical medicine.)

The Cultivation of the Human Entamœbæ.

A VERY important advance in tropical medicine, and one of which due notice must be taken in these columns, is that the entamœbæ of the human intestine have been successfully cultivated *in vitro*. Prior to 1924 several workers had claimed partial success with different methods, but it has remained for Drs. W. C. Boeck and J. Drbohlav in America to achieve full success. In connection with this very important discovery, it is most unfortunate that its original announcement appears to have been shrouded in that uncertainty which so

besets the literature on the entamœbæ of man. The first successful cultivation of a true entamœbæ—as distinguished from cultivation of free-living amœbæ—was that of Barret and Smith (1924) of *Entamœba barretti* of the turtle.

At the 20th annual meeting of the American Society of Tropical Medicine, held at Chicago in the summer of 1924, Dr. Boeck read a communication on June the 10th, 1924, on the successful cultivation of *Entamœba histolytica* of man *in vitro*. Of this, the only notice taken was a mere note in the published minutes of that meeting. Meantime, Dr. Drbohlav returned to Europe, and at a meeting in November 1924 of the Royal Society of Tropical Medicine and Hygiene in London, and afterwards at a meeting in Paris of the Société de Pathologie Exotique in February 1925, he demonstrated the technique employed and the living entamœbæ in artificial culture *in vitro*. The journals of both societies published preliminary notes on the subject, giving the composition of the media used, but only scanty details.

These publications aroused universal interest; and Boeck and Drbohlav's technique was adopted by many laboratories all over the world. Although detailed papers on the subject were promised for publication in the *American Journal of Tropical Medicine* and in the *Annales de Parasitologie* in 1924-25, they failed to appear in these years. The experiments were repeated by Professor Dobell and Dr. Wenyon in London, by several workers in France, America, and the Philippines (and at the Calcutta School of Tropical Medicine). In brief the work of Boeck and Drbohlav was confirmed by many different workers in many different countries before their full paper was finally published. This final and detailed publication, illustrated with numerous and beautiful micro-photographs, finally appeared in the *American Journal of Hygiene* for July, 1925, Vol. V, No. 4, p. 371; and laboratory workers interested in the subject should refer to this, the full and detailed original account of the subject, rather than to the earlier and more scanty information available.

Cultivation of *E. histolytica* was first obtained by accident. A stool was cultivated in the medium first employed by Boeck for intestinal flagellate protozoa, and it was found that motile *E. histolytica* grew in this culture medium. Further experiments were made, and a standard medium elaborated. The procedure finally adopted and recommended is as follows:—

Four eggs are sterilised on their surface (with alcohol or by other means), and their entire contents aspirated into syringes and emulsified with 50 c.c. of Locke's solution. This fluid is then distributed into sterile test tubes in the usual way, sloped and set by heat. (Or Dorset's egg medium, or ordinary bacteriological blood-agar can be substituted). This constitutes the solid basis of the medium. Its fluid constituent consists of inactivated serum (human or horse) diluted 1 in 8 with Locke's solution; or egg-albumin diluted with Locke's solution (the white of one egg to a litre).

The solid medium, after tubing, is sterilised in the autoclave, and the liquid medium subsequently added, 2 to 3 c.c. being poured over the surface. If there is any reason to doubt the sterility of the serum or fluid element it may be filtered through a Berkefeld filter candle, (but this has proved not to be necessary with sera used at Calcutta and collected under ordinary aseptic precautions).

The tubes of culture media, thus prepared, are then kept warmed in the 37°C. incubator,—a most essential step, since only warmed media should be inoculated. They are inoculated by picking up a piece of mucus containing motile, vegetative *E. histolytica*, or a suspected bit of mucus from a dysenteric stool, in a capillary pipette, and inoculating into the bottom of the fluid constituent of the medium, in which the greatest growth of the entamœbæ takes place, at the interface between solid and liquid medium. The cul-

tures should be incubated aerobically at 37°C. (It is to be noted that any slight drop in temperature kills off the cultures at once; thus at the Calcutta School of Tropical Medicine it has been noted that active, rich cultures full of motile *E. histolytica* died off in a night, when the gas supply to the incubator failed, and the temperature fell).

The maximum growth of *E. histolytica* occurs in such cultures at from 24 to 48 hours after insemination. In order to examine them, a little of the sediment at the bottom of the tube should be removed with a sterile capillary pipette and examined under the microscope. After this period the entamœbæ die off rapidly—(probably from bacterial overgrowth),—but sub-cultures should be taken every 2nd, 3rd or 4th day, and in this way strains have been kept alive by different workers for periods of some months.

Under such conditions Boeck and Drbohlav found that not only did *E. histolytica* thrive and multiply very rapidly, but the medium proved suitable for the cultivation of *E. gingivalis*—the common entamœba of the mouth, and of such common intestinal flagellate protozoa as *Trichomonas* and *Chilomastix*. In all their work—as in the work of other subsequent investigators—*Blastocystis hominis*, an exceedingly common fungus of the human intestine,—has proved a tremendous drawback: if present it will overgrow the culture in 48 hours, killing off or starving out the entamœbæ and flagellate protozoa.

The classical work of Dobell has shewn that, when it lives in the mucosa of the colon, *E. histolytica* is a parasite whose protoplasm is bacteriologically sterile. In stale stools in cases of amœbic dysentery bacteria may be seen to have invaded the dying and vacuolated entamœba, but in its pristine freshness, *E. histolytica* is a selective and dainty feeder, subsisting upon the tissue juices dissolved by its powerful proteolytic ferment, or upon ingested red blood corpuscles; never under such circumstances does it ingest bacteria.

In culture, however, whilst its morphological characters remain absolutely true to type—with its active travelling power of movement, its voluminous pseudopodia consisting of clear ectoplasm only, and its delicate nucleus, invisible in a saline preparation,—yet it now takes on an extraordinary power of ingesting and feeding upon bacteria. Under cultural conditions it will very readily ingest red blood corpuscles when presented to it, but its appetite now appears to have become depraved, and it feeds upon bacteria. (What so wonderful a change in the habits of this entamœba mean, it is difficult to say. It appears as if the entamœba, faced with an entirely new and unnatural environment, possesses powers of adapting its habits to this sudden change of environment; in the tissues, with the rich nutrition of digested tissue cells available, it subsists upon this source of nourishment; in culture, with no tissue available, bacteria become its prey. Every worker who has studied the subject will readily confirm Boeck and Drbohlav's observation that in culture *in vitro*—but not as it exists in the tissues of the colon mucosa—*E. histolytica* ingests bacteria. Yet it remains true to type as *E. histolytica*; it never simulates *E. coli* or any of the other human intestinal entamœbæ).

Using the methods outlined, the authors were able to cultivate two strains of *E. histolytica*; one kept alive through 152 sub-cultures from February 18th till October 1st, 1924; the second through 42 sub-cultures from July 2nd till October 1st, 1924. Throughout *E. histolytica* remained from first to last true to morphological type, whilst inoculation of the cultures into the rectum of kittens produced typical amœbic dysentery. One such kitten indeed developed not merely amœbic dysentery, but also liver abscess as the result. From these infected kittens the same entamœba was obtained in cultures on artificial media. Hench Koch's postulates were complied with, and the cultural strain proved to be identical with the original strain infective

to man. A sub-culture at the fifth month of sub-passage was still infective to kittens. At no time did the entamœbæ encyst, and all attempts to induce them to do so by exposing the cultures to different conditions of temperature failed.

There can be no doubt from the details of this work that *E. histolytica* can now be readily cultivated in artificial media *in vitro*. The story is carried a considerable step further by the publication in the *Journal of Tropical Medicine and Hygiene* of October 1st, 1925, Vol. XXVIII, No. 19, p. 345 by Drs. J. G. Thomson and Andrew Robertson, of a paper dealing with the cultivation *in vitro* of different species of entamœbæ of the human intestine by Boeck and Drbohlav's technique. These authors have succeeded with this technique in cultivating *in vitro* *E. histolytica*, *E. coli*, *Endolimax nana*, *Dientamœba fragilis*, and—probably—*Iodamoeba butschlii*. The following are some of their observations with regard to the motile forms of these entamœbæ as seen in culture:—

E. histolytica.—"When actively motile, *E. histolytica* became stretched out in a ribbon-shape with blunt, rounded ends. The ectoplasm, while clearly differentiated from the endoplasm, yet tended to maintain the general outline of the amœba. That is to say, the blunt rounded anterior end, consisting of the ectoplasm was the same width as the remainder of the body. Movement was usually more or less direct, not as in some of the other species, indeterminate, and the distance covered considerable. The nuclear structure was always of the same type as that found in man, but the body showed greater vacuolation and also contained ingested bacteria." (In brief, *E. histolytica*, in its actively motile, vegetative state, tends to travel across the microscope field, whereas the other species do not).

E. coli.—"They appeared to be very susceptible to changes in temperature and if placed on a slide which was more than three or four degrees below 37°C., they rounded up and withdrew their pseudopodia. When actively motile, they shewed a clearly marked differentiation between the clear hyaline ectoplasm and the coarsely granular endoplasm. In view of the old conception of *E. histolytica* having a much more clearly defined ectoplasm than *E. coli*, the large amount of ectoplasm shewn by the majority of the cultured *E. coli* was striking. They did not tend to progress across the slide, but moved about over the same spot, extruding their large, blunt, rounded pseudopodia in all directions. Their movement was, in comparison with that of the other species, sluggish and ponderous. The body was usually rounded and seldom adopted the wide ribbon or band-like outline of *E. histolytica*, and, if it did, it soon returned to the rounder or more compact shape."

D. fragilis.—"The movement is characteristic. Dientamœbæ do not tend to cover a great deal of ground, staying rather in the same position, extruding pseudopodia in an aimless fashion in all directions. The pseudopodia are pushed out suddenly, but not any great distance. In outline they are conical, and, as soon as the pseudopod has reached the extent of its travel, it usually widens, so that a flattened band of ectoplasm surrounds a considerable part of the circumference of the body.

From the wide, flattened, leaf-like pseudopodium, other conical processes may come out, still further accentuating the crenated leaf-like appearance."

I. butschlii.—"The movement is very similar to that described in the case of *E. histolytica*. The amœba is usually stretched out in an elongated form, and is rather wider towards its posterior end. The pseudopodia are blunt, about the same width as, or a trifle less than the width of the body, and are composed of clear hyaline ectoplasm. The direction of movement is chiefly straight, and if the amœba meets with an obstruction, it attempts to shove its way through, rather than withdraw and change its shape, as *D. fragilis* would do. The body is vacuolated and may contain bacteria etc."

E. nana.—"Just as the movement of the cultural *Iodamoeba* closely paralleled that of *E. histolytica*, so does that of *E. nana* bear a resemblance to that of *E. coli*. The amœba tends to remain compact, while the wide pseudopodia are extruded in aimless fashion in all conceivable directions. It changes its situation slowly, preferring to remain in one spot."

(It will be seen that we have in this series of published papers a most important set of contributions to the study of the entamœbæ of man, and to tropical medicine. Thus:—

(1) The possibility of cultural diagnosis replacing direct examination of the stools for the identification of infection with entamœbæ and flagellate protozoa.

(2) The study *in vitro* of the complete life cycles of the intestinal entamœbæ and flagellate protozoa of man, in connection with which several points require to be cleared up, such as, for example, the discovery of the method of de-excystation of the intestinal entamœbæ.

(3) The determination of the exact number of species of entamœbæ and of flagellate protozoa which parasitise the intestine of man; seeing that their complete morphology and differentiation may possibly be determined by their characters in culture.

(4) The study of the action *in vitro* upon the parasite of amœbic dysentery and amœbiasis of different drugs reputed to have a therapeutic action in amœbic infection in man, with a view to improving lines of treatment of the disease.

During 1925 at the Calcutta School of Tropical Medicine, *Embadomonas* has been once cultivated *in vitro* by Boeck's technique; *Enteromonas* on three occasions, *Trichomonas* and *Chilomastix* frequently, *Giardia*—so far—never; *E. histolytica* frequently. In fact a year's experience of the results of Boeck's methods has shewn that cultural diagnosis of the intestinal protozoal infections of man is not merely a feasible procedure, but possibly a better procedure than the direct examination of stale stools.

It is certain that this series of important papers on the cultivation of the entamœbæ of man *in vitro* will be followed by further investigation into these interesting and important parasites.)

The Uses of Kaolin.

We have received, through the courtesy of the Rev. Henri Monnier, Basrur, South Kanara, a copy of a MS. by Dr. Victor Kuhne, Laureate of the Faculty of Geneva, and formerly Chief of the Swiss Medical Mission to Serbia during the war, dealing with this subject. We understand that the original MS. has been submitted for publication elsewhere, whilst it is so enthusiastically in favour of the use of kaolin for a multitude of conditions that it is scarcely suitable for publication *in extenso*. Yet certain abstracts from it may be of interest to our readers, since there is no question as to the value of kaolin as a simple and cheap and reliable form of treatment in several tropical diseases:—

Clay, he claims, of which kaolin or porcelain earth is the purest chemical preparation, may almost claim to be a universal panacea, so many and so varied are its uses. It has been in use since the earliest dawn of medical history; Discorides of Cilicia, who lived about the dawn of the Christian era, describes five different kinds of clay in medicinal use in the 5th tome of his *materia medica*. Galen attributes its discovery to Hermes Trismegistes, the teacher of Æsculapius. Avicenne, most famous of Arab physicians (980 to 1039 A.D.), describes the various kinds of clay in medicinal use in his era. In the middle ages it came to be extensively used for all sorts of complaints, such as epilepsy and cardiac diseases, and not unnaturally fell into disrepute under such improper usage. Subsequently in slight demand as an excipient for pills and pastes, it has remained for Stumpf of

Wurzburg in 1898 to almost re-introduce this valuable medicament to the profession.

His attention to its value was first drawn by noting in 1882 that a corpse which had been buried for 37 months, and which was then exhumed for medico-legal examination, had been buried in a clay soil and was in a most extraordinary state of preservation. In 1886 he commenced to use clay as a paste in the treatment of old-standing septic wounds with most gratifying results as to deodorisation, protection from irritation, and healing. Chemically kaolin is silicate of aluminium, very stable in composition, insoluble in water, and not absorbed into the system on oral administration. Theoretically, unlimited quantities may be given by the mouth with no untoward results. The inhabitants of Tierra del Fuego are reported to eat from $\frac{1}{2}$ lb. to 1½ lbs. of clay per diem during the two or three months of their rainy season, when other sources of nutrition fail, and to shew no ill effects.

In 1900 Stumpf began the internal treatment of cases of cholera, dysentery and diarrhoea by oral administration of kaolin. During the period after the Treaty of Bucharest, when the Serbian armies returned to their homes, Dr. Kuhne was in charge of a cholera camp in Belgrade and also of a similar one at Nish. He records how there was introduced to him one evening "a small man, some 50 years old, who introduced himself as a Professor at Wurzburg,"—Dr. Stumpf, and begged to be allowed to treat the cholera cases with kaolin. Cases which were apparently desperate were handed over to him, with the result that next day they were not dead, but recovering. "I heard the little man repeating with a persistence truly Teutonic the word 'gout'—the Serbian for 'swallow'—to his patients, apparently under the impression that it was the equivalent for the German word *gut*, (good)." Persevering in this line of treatment, the mortality in these cholera camps dropped from 44 per cent. to 3 per cent. It proved far more efficacious than injections of anti-serum, injections of iodine, or hypertonic saline treatment. Also it was far more practicable.

Clinically, writes Dr. Kuhne, the immediate diagnosis of cholera from the symptoms shewn by the patient is of far more importance than to wait for a—possible—bacteriological diagnosis; one has to act at once. He writes that he has now adopted kaolin treatment in all general cases of intestinal disorder in place of iusmuth, charcoal, talc, etc. In the treatment of cholera, the following prescription is advocated:—

Into 250 c.c. of cold boiled water pour 100 gms. of finely pulverised kaolin. This is shaken until a perfectly homogeneous, yellow white creamy liquid is obtained. A tumblerful of this mixture is given to the patient orally every half hour or every hour to six or more doses. As a rule, after the sixth dose the patient falls asleep and all acute symptoms are over. The treatment is continued with smaller dosage over the next few days and the patient should be able to leave hospital in from 5 to 10 days' time. If it should prove impossible to administer the emulsion by the mouth it may be given by the stomach tube or by enema,—giving at least three litres of the suspension per dose in the latter case. When making the emulsion the kaolin should always be added to the water, and not vice versa. Other accessory treatment the author considers to be superfluous. For the first 18 hours after the admission nothing else should be given by the mouth except plain cold water.

The advantages of kaolin treatment—if it be as successful as the author claims—are obvious. It can be administered by anyone, even by the patient himself; accurate dosage is not necessary; in an hour a medical attendant can deal with a hundred patients; the treatment is not painful, is free from danger, and requires no special appliances; it can be used as a prophylactic measure; it is equally applicable to all forms of diarrhoea and dysentery; lastly, it is very cheap. Should

the true diagnosis be choleraic diarrhoea and not true cholera, only good and not harm is done.

In action kaolin probably owes its value to (a) adsorption on the surface of its fine molecules of toxins; thus, it is of great value in cases of food poisoning also; (b) its mechanical protective coating of the acutely inflamed gut. Finally, the range of therapeutic application of kaolin is not confined to intestinal disorders; it is of value in infantile diarrhoea; as a local application in diphtheria of the throat and on burns; for local treatment in leucorrhoea and in vaginal and uterine inflammation; and lastly, for disinfection of the surgeon's hands before operation, where thorough rubbing of the hands with purified kaolin will—it is believed—remove all septic infection from the skin without causing the irritation of the skin so common with the use of the usual surgical antiseptics.

(Dr. Kuhne's article, as may be gathered, is very much on the laudatory side. Personally we have now been using kaolin in the treatment of intestinal disorders for some two years—especially in the treatment of bacillary dysentery. Morson's electrically precipitated "Osmo-kaolin" is probably the best preparation. It may be said that such treatment is exceedingly well tolerated by the patient; is often very successful from a clinical point of view; and is a measure of distinct therapeutic value. The usual dose given is two drachms suspended in water or milk every four hours during the acute dysenteric phase).

On sending Children to Jail.

FROM time to time, in our columns devoted to reviews of annual reports, we review those from different Inspectors-General of Prisons of different provinces in India. For several years past they have dwelt especially upon one terrible and constant inhumane practice in legal procedure in India; the sending to jail of children or young juvenile offenders against different sections of the Indian Penal Code. No one defends this practice; everyone admits the urgent necessity for reform; but—as usual—"financial considerations are of paramount importance." It is nevertheless high time that this old standing iniquity was remedied. It is one which must have come prominently to the notice of every jail superintendent in India, i.e., of nearly every civil surgeon in India; yet little or nothing is done to remedy it.

In an address to the Bengal Presidency Council of Women in the Council Chamber at Government House, Calcutta, on the 10th December, 1925, Lieutenant-Colonel W. G. Hamilton, I.M.S., Inspector-General of Prisons, Bengal, summarised the whole position in an important and forcible address. The following abstract of his lecture is taken from *The Statesman* for the 11th December, 1925:—

"The Government of Bengal strongly disapproves of the practice of imprisonment of children for petty offences, but unfortunately funds have not been available to make the Children's Act effective. We are all proud of our connexion with this great city of Calcutta and we like to think and speak of it as the second city of the Empire. I am afraid, however, that in our treatment of the youthful offender we are a long way behind Madras, which ignorant people (usually those who have never been there) refer to contemptuously as 'the benighted Presidency.'

"Young children of seven, eight and ten years of age in Calcutta have been sent to prison for the most paltry offences. Your own council reported one case of a little girl who was sent to the Presidency Female Jail. I could quote several similar cases, but will only mention three which I came across about two weeks ago during a casual visit to the Juvenile Jail. I saw one small boy about eleven years old, and asked what was his offence and what sentence he was undergoing. To my surprise I found that he was convicted under section 109 of the Criminal Procedure Code, a

section that is usually enforced in the case of notorious habitual criminals who have no ostensible means of livelihood and are suspected of living a life of crime, and unless they can get someone to be surety for their good behaviour they are committed to prison, usually for six months or a year's simple imprisonment.

"On inquiry I found that this small boy had one previous conviction, probably no friends. It would be impossible for him to get any one to go surety for his good conduct. It is very difficult to understand how such a case can be committed under section 109. But that is not all, he cannot be sent to a reformatory school because it cannot take cases committed under this section. That means that unless he is released by Government he will have to undergo six months' simple imprisonment. To my mind, so-called simple imprisonment is the most pernicious form of imprisonment, it means that the prisoner is not compelled to work. Can you imagine anything more demoralising and degrading than for a boy or man to idle, doing nothing for six months or a year? It is true that in the Juvenile Jail we make them go to school but we cannot teach them any useful work or trade unless the prisoner consents to do it. I have reported this case to Government, I hope action will be taken.

"The other two cases are examples of committal to prison for breaches of local Police Acts, not criminal offences in the strict sense at all. These cases are usually for street obstruction, gambling in the street, begging, being in charge of bullocks or horses with sores on their back or which are lame, etc.

"The two cases I had reported to me were two little boys of about 12 years of age, they were convicted of street obstruction and were sentenced to a fine of eight annas or in default six days' simple imprisonment. These short sentences are absolutely useless. I cannot imagine anything more futile than to send a child to prison for three or four days. It is neither deterrent nor reformatory. It seems a deliberate attempt to accustom a child to jail and to turn him into a professional criminal. If we send young children to prison for such paltry offences, I do not think we have made much advance on the days I described of 1735, one hundred and ninety years ago.

"Magistrates say 'What are we to do, we disapprove of imprisonment of young children as much as you do, but until the Children's Act is brought into force we have no other alternative than to commit children to prison. Sometimes they have been let off with a warning and again they commit an offence. If we discharge them, the law is a farce.'

"I fully admit that it is the system that is at fault, but surely it should not be beyond human ingenuity to devise some other means than imprisonment for convicting young children who beg, obstruct the pathway or gamble in the streets. I cannot help thinking that if it was possible for social workers to attend the Police Courts and inquire into every case of a child brought up before a magistrate, it would be possible in many cases to avoid the evils of imprisonment. I am not a sloppy sentimentalist who deprecates the conviction or punishment of erring juveniles. I am a strong believer in children being put under discipline. I think many of the troubles of the present day are due to the lax control of children by their parents. But we should be rational and humane in our methods and not fall back on the obsolete system of sending little children to prison for every petty breach of a local law, or Police Act.

"I confess that in the past the Juvenile Jail has been too much a penal institution and not enough was done to try to reform the boys committed to jail. The school-rooms were dark and badly ventilated, the cubicles for sleeping were miserable hovels, dark and forbidding. Some unsuitable forms of labour for boys were in force, such as oil-pressing and wheat-grinding. The principal industry, quinine-tablet making, was useless to them after discharge from jail. Ordinary prison clothing was worn by the inmates. Some of

the jail punishments were not in conformity with modern ideas for the correction of the youthful offenders.

"During the past year I have abolished oil mills and wheat-grinding. The quinine industry has been removed, the rooms formerly used for the manufacture of quinine—which are bright and well ventilated—have been converted into school-rooms and the old school-rooms are now used as dormitories. Ordinary jail uniforms have been replaced by a special uniform which is different from the old pattern. In future it is proposed to run the jail on modified Borstal lines.

"A list of special rules has been drawn up and submitted to Government for approval. I hope to develop the recreative side of the jail, to encourage manly outdoor games, and also to get permission to allow lectures and instructional lantern or cinema exhibitions. His Excellency visited the jail about a year ago, I showed him the sleeping cubicles, he condemned them as unfit. The cost of reconstructing these cubicles into more suitable dormitories will be about Rs. 70,000. Recently the Legislative Council passed a vote for Rs. 45,000 to start the necessary alterations. Although we have made these few improvements during the past year, there are still many serious defects which should be remedied.

"Under-trial prisoners are sent to this jail. There is no separate accommodation for them and it is difficult to separate them completely from those who have been convicted.

"Juvenile offenders under trial should not be sent to a jail at all, even a juvenile jail is objectionable. There should be sufficient remand homes to accommodate all the juvenile under-trial offenders of Calcutta, and the suburbs.

"I hope it will be possible to provide sufficient remand homes and thus do away with the present objectionable habit of keeping boys under trial in a jail.

"Some arrangement should be made for a separate yard or division of the jail to accommodate star class prisoners. The whole object of this class is to keep them absolutely separate from those of more criminal tendencies. We hope in the future to start a Borstal Institution for adolescent criminals at Bankura. It is proposed to convert the present district jail for that purpose. Special legislation will be necessary to enable courts to commit suitable cases direct to the Borstal Institution. Probably a Bill on the lines of the Madras Borstal Bill would be suitable.

"There are several other points such as the provision of more children's courts. The children's court in Lower Circular Road only deals with a comparatively small number of the youthful offenders in Calcutta. Magistrates with special qualifications for dealing with children should be selected.

"The Salvation Army have offered to run a Home for 50 boys and 50 girls convicted under the Children's Act 1922. The estimated cost is Rs. 1,100 per mensem or Rs. 13,200 per annum. This home I take it would be a certified school under the Act. I think if Government approved one scheme and could find the money, the great obstacle in the way of prevention of imprisonment of children would be removed.

"One of the most important problems of the youthful offenders is their after-care on discharge from a jail or Borstal Institution.

"What is needed in Calcutta is a special After-Care Association for juvenile offenders. It should be run on the lines of the Borstal associations of England or Madras. I want you all to realise that however much we may improve our jails in the future and however much we may reform our young criminals, all our money and efforts will be thrown away unless there is some society to give them a helping hand when they are discharged from prison or a Borstal Institution. Otherwise they will be driven by circumstances to relapse into crime and return to jail. Their real punishment will begin when they are released from jail unless there is someone to look after them."

Prophylaxis of Whooping-Cough.

British Medical Journal, May 30, 1925.

V. GILLOT (*Bull. Acad. de Med.*, February 10th, 1925, p. 176), has had recourse to a new and very simple method which consists in subcutaneous injection of whole blood into children who have been exposed to infection. The blood may be taken from a person who has had whooping-cough at some time in his life, or from one of the parents without troubling to inquire if they have had whooping-cough or not. During a severe epidemic of pertussis at Algiers in 1924 Gillot employed this method at the children's clinic with the following results: (1) All the children who were injected before the period of invasion were protected against the disease. (2) Those who were first injected at the onset had very mild attacks. One injection was given, the dose ranging from 2 to 5 c.cm.

Quinine Bihydrochloride Combined with Pituitary Extract in Labour.

By T. J. RYAN.

(*Practitioner*, June 1925, p. 438.)

THE remarks deal only with normal vertex presentations.

Having made certain that no obstruction to delivery exists, and then having considered it wise to hasten delivery, two alternative treatments are suggested. First, to give of. ricini 1 oz., followed by a hot drink, two hours later an enema of soap and water, one hour later a cachet of quinine bi-hydrochloride grs. v, the latter to be repeated every two hours till grs. xv have been administered. If labour does not come on strongly, hot fomentations applied over the abdomen usually bring on strong labour pains.

When the os is the size of at least half-a-crown (but not before), give a deep intra muscular injection of pituitary extract, 1 c.c. Full dilatation usually occurs speedily with an uneventful delivery.

The second all-Bengal Kala-Azar Conference.

At the opening of the conference, His Excellency Lord Curzon, the present position of the Government of Bengal with regard to the ravages of kala-azar in the Province. The following abstract of his address is taken from *The Statesman* of the 22nd November, 1925:—

In addressing the conference, which was attended by several hundred members, including many prominent Government officials, His Excellency said it was not until about 20 years ago, that investigations, which had been going on for some time previously, established the existence of kala-azar as a disease distinct from malaria, and a satisfactory treatment for dealing with it was discovered so recently as 1915.

"It is only in comparatively recent times," he continued, "that public attention has been focussed upon the problem. Its symptoms are known to be very similar to those of malaria and the discovery of a treatment in 1915 was a factor of far-reaching importance, as it has brought the subjugation of the disease within the realm of practical politics, provided of course that the agencies for using that treatment can be adequately organised. Indeed the success of the treatment may be judged by the fact that whereas previously 96 per cent. of the cases were fatal, 95 per cent. of those treated now recover.

"The knowledge of its symptoms and the discovery of a comparatively easy guaranteed treatment naturally resulted in a large increase of reported cases and this fact, coupled with the usual human tendency to magnify the importance and seriousness of any new discovery, naturally led to alarming views as to the prevalence and possibilities of the new disease. In saying this, I have no desire to underestimate the importance of the problem or the necessity for concentrating attention

upon it, but we must guard against the mistake of regarding it as the only, or even the chief, problem with which we have to deal, to the exclusion of the many other problems connected with public health.

"Malaria is still the root problem disease in Bengal, but with that terrible scourge undermining the health of so large a proportion of the population, everything that is humanly possible must be done to prevent the addition of another serious epidemic fever. At one time kala-azar threatened to become an even more deadly enemy to health than malaria, but the discovery of a sure remedy has rendered the problem of its treatment mainly a question of organisation and that is why such a conference as this is so particularly valuable. How can we best utilise our resources; how can we best train men to handle the remedy, how can we most most effectively bring the remedy within reach of the sufferers? These are the kind of questions which you have to consider and your discussion of these matters will be of the utmost value.

"A problem of so vast a nature as this is incapable of solution by the efforts of Government alone. Government can do no more than carry out research and train men in the treatment of the disease. Government, through its officers, can investigate the prevalence and scope of the disease and undertake the research work necessary for discovering its causes, the conditions favourable to its growth, the steps which will prevent its development and the treatment which will cure it. This is perhaps the best service we can render. We can also provide facilities for training doctors and other workers in the methods which experience has found effective, and thus supply the pioneers in the practical work of treatment. Men so trained will be able to point the way in the initial stages of the disease and advise local workers in the light of their own experience. The ideal we should aim at, I think, is the establishment of a model anti-kala-azar centre in each district head-quarters. Having laid the foundation in this way, Government must necessarily leave it to honorary workers and local organisations to amplify the work on an extensive scale and carry it into every village.

"To what extent has the Government of Bengal hitherto carried out its obligations in this matter? In the first place they carried out a survey which gave us a rough idea of the prevalence of the disease and the areas mainly infected. They have undertaken research work, which has made known the symptoms and nature of the disease and the treatment most successful in curing it. They have drawn up a scheme of anti-kala-azar measures, and by insisting on the appointment of District Public Health Officers they have enabled a beginning to be made with a sound scheme for the treatment of the disease. Facilities are provided at the School of Tropical Medicine or under Civil Surgeons or Health Officers with recent experience of kala-azar work for training medical officers who may be deputed there by the local bodies.

"The Public Health Department has an Assistant Director with a staff of 4 assistant and 17 sub-assistant surgeons who, though not engaged solely in kala-azar work, carry out inspection in districts and advise local agencies in their work. Lastly, the Government has given financial assistance to local organisations engaged in the campaign. It is for you now to consider what further assistance Government can render and in what way local efforts may best be encouraged and directed.

"It would appear to be both economical and effective for the local agencies and voluntary workers to carry on the work under the continued guidance and supervision of the Public Health Department on the lines which experience has found to be most effective, and I am glad to say that in recent years several local bodies and organisations have shown a very practical recognition of their responsibilities and have done excellent work in combating the disease. I desire in particular to express my sincere appreciation of the work of the Central Co-operative Anti-Malarial Society.

This Society had 67 centres in operation for the voluntary treatment of villagers in 1924 and the Bengal Health Association has 24 kala-azar centres. Government have been able to give both these Societies grants during the last two years to help them with their work. Various District Boards also have shown a commendable enthusiasm in the furtherance of the campaign.

"The fact that this problem now arouses such keen interest in the public justifies the hope that in the next few years the combined efforts of Government and local bodies will not only stop the spread of this disease but greatly reduce its present incidence. The Co-operative Anti-Malarial Society and the Bengal Health Association have already done splendid work, and I have no doubt that with further assistance they will be able to expand their present activities. The grants of Rs. 30,500 which we made this year have been so well utilised that we have the strongest grounds for increasing them, and we have now under consideration the question of obtaining a larger provision in next year's budget for the purpose of assisting the two associations and the local bodies in their splendid work.

"There is still a very great deal to be done both by Government and by other agencies, and I would urge those associations and bodies to take heart in the knowledge that their work is appreciated and will be supported. Government on its side will continue to give the utmost possible financial assistance, to provide facilities for training medical officers, inspection and guidance, and they will undertake further research work. We have still to discover the vehicle by which infection is conveyed, and it is to be hoped that the expert commission which was appointed by the Government of India last year to investigate this aspect, and towards the expenses of which like other Governments we made grants, will succeed in identifying the vector. If they are successful, the administration of medical treatment and the general scheme of operations will be very greatly benefited by the discovery."

Sir Kailash Chandra Bose, Kt., C.I.E., O.B.E., President of the Central Co-operative Anti-Malarial Society, in thanking His Excellency for his continued interest in the conference, said:—"Malaria is alone responsible for enfeebling the Bengali race; it has indeed sapped out the vitality of the nation. It has depopulated our *Sonar Bangla*. Most of my friends would require an interpretation of the phrase *Sonar Bangla*. During the full harvest the paddy fields cultivated by a sturdy and healthy race of peasants looked like a canopy of gold spread over the earth. It might be also explained that our paddy brought to us gold and diamonds. The peasantry is almost now annihilated. Malaria has almost deprived us of our agricultural prosperity. It has virtually impoverished us in our national wealth. Infant mortality, premature decay, sterility, and untimely death prevent the people reaching their ancient old age. 'Malaria is the chieftain of diseases,' for the average life of Indian is only 22 years now. Much of our peasantry still left after the ravages of malaria is threatened with extinction by attacks of her offspring kala-azar.

"Malaria is the cause of the perverted state and degraded mentality of the people of Bengal. To eradicate malaria should be the order of the day. We all know that timely kerosinisation annihilates the species of anopheles which are responsible for the spread of the disease, and the suspension of the process favours the growth and outbreak of malaria. When kala-azar breaks out in a village in an epidemic form, we can easily check its progress by a systematic and simultaneous treatment of the people affected in a centre started on co-operative principles."

"Caprokol."

"CAPROKOL" is hexyl-resorcinol, prepared by the British Drug Houses, Ltd., and introduced into medical

practice as a new, reliable and efficacious urinary antiseptic. The attention of the medical profession to the value of hexyl-resorcinol was first drawn by Dr. R. B. Henline in a paper published in the *Journal of Urology* for August, 1925. This substance may be said to fulfill all the requirements of the ideal urinary antiseptic better than any other at present known; it is stable in composition, being a white solid, withstanding repeated distillation under diminished pressure; it is bactericidal in high dilutions in urine of any reaction; when administered by the mouth it is non-toxic; it is non-irritating to the urinary tract; it is eliminated in high percentage by the kidney, and a continuous flow of bactericidal urine is secreted not infrequently for as long as 24 hours, following a single dose of hexyl-resorcinol. Finally, it may be given in repeated doses for indefinite periods with safety.

With the guarantee of the British Drug Houses behind it, this new product should prove of great interest to the medical profession in this country. It is prescribed, either for adults in flexible gelatine capsules each containing 0.15 grm. of caprokol in a 25 per cent. solution in olive oil; or for children in a 2½ per cent. solution in olive oil, the dose being taken floated on milk. The dose for an adult should be at first 2 such capsules, immediately after each meal; later increased to 3, or a maximum of 4 capsules, t.d.s. It should be taken either immediately after food, or after a glassful of milk. Fluid intake should be in general restricted, and alkalies are contra-indicated with it.

Some of Dr. Henline's results are of very considerable interest. In 26 cases of *B. coli* infection, the average duration of infection was 3.7 years; except in two cases the urine became bacteriologically sterile on culture in an average of 63.5 days of caprokol treatment. In 12 cases of infection with staphylococcus, streptococcus, *B. proteus* and the like, the average duration of the infection was 2½ years; after caprokol administration was begun the urine became culturally sterile in an average after 50.7 days' treatment. He concludes as follows:—

1. The necessity for a complete urological examination in infections of the urinary tract, including cultures, kidney functional tests, and complete x-ray pictures, is of the utmost importance before any treatment is instituted.

2. Hexyl resorcinol is an effective internal urinary antiseptic administrable by the mouth, non-toxic, non-irritating to the urinary tract and a valuable aid in the treatment of urinary tract infections. It is apparently superior to all other urinary antiseptics described.

3. Hexyl resorcinol is bactericidal for all the usual organisms infecting the urinary tract. An average of 63.5 days for *B. coli*, 18 days for *Staphylococcus aureus*, 94.5 days for *B. proteus*, 91 days for *B. lactis aerogenes* and 133 days for mixed infections was necessary to sterilize the urine. Only one case recurred, and in this one treatment was discontinued too soon. Ninety-two per cent. were cured. Of the three which were not cured, one did not return for treatment, one still had a growth of *B. fluorescens*, and one was complicated by a bladder tumour. These three are clinically cured.

4. The duration of the disease apparently has no bearing on the length of time necessary to affect a cure, providing the renal parenchyma has not been damaged.

5. Hexyl resorcinol, by thorough disinfection of the urinary tract, is an aid in preventing recurrent stones.

6. In post-operative urological cases, hexyl resorcinol is an aid in healing wounds in streptococcus infections.

7. The series of cases of gonorrheal urethritis is too small for definite conclusions, however hexyl resorcinol is apparently of little if any value in the treatment of gonorrheal urethritis in the male.

Reviews.

THE LIFE OF SIR WILLIAM OSLER.—By Harvey Cushing. Vols. I and II. Oxford: Clarendon Press, 1925. Price, 37s. 6d.

WILLIAM OSLER, the youngest son of a parson with nine children, was born at Bond Head in Canada on July 12th, 1849. He was sent to Weston School; in that he devised every possible means of avoiding his school work, he was a thoroughly bad boy; he was, however, a great athlete. Even in these days he showed a great interest in biology. He entered Trinity College, Toronto, with the intention of going into the Church, but abandoned this intention and entered the Toronto Medical School in 1868. His main interests were biology and anatomy and had he come under the influence of, say, Huxley it seems probable that he would have abandoned medicine altogether in favour of biology, as it was apparent that lectures bored him. In 1870 he left Toronto for the McGill Medical School where in 1872 he took his degree. In the same year he visited Great Britain for the first time. During his first visit he spent his time visiting hospitals and gaining practical experience; in one of his letters home he wrote protesting against the practice so common amongst his countrymen of spending their time grinding to pass English examinations. However at a later date he himself succumbed and took his M. R. C. P. From London he went on to Berlin and thence to Vienna. In Berlin he was much impressed by the post-mortem demonstrations of Virchow, but was not impressed by the German capital itself; on the other hand Vienna as a town impressed him, its general sanitary condition standing out in marked contrast to that of Berlin, but he was not impressed by its post-mortem demonstrations. He returned to Canada in 1874 and took up an appointment at McGill University; here he was at first a teacher of medicine and later, pathologist. The following year he had small-pox. His great interest in pathology developed, especially in relation to the autopsy room, and his first published volume was a collection of pathological reports which he dedicated to Dr. James Bovell, M.D. In 1878 he was again in London for a short time.

As a physician to the Montreal General Hospital he was allowed to carry on a consulting practice but apparently he did not encourage these consultations, and the students who lived with him at the time are reported to have said that they can only remember three consultations having taken place in his rooms. It was said of him that "he had the greatest contempt for the doctor who made financial gain the first object of his work" and "even seemed to go so far as to think that a man could not make more than a bare living and still be an honest and competent physician." He remained at Montreal until 1883; during this period he was made a Fellow of the Royal College of Physicians, London. He again visited Europe in 1884, made the acquaintance of Koch and again met Virchow. He now left his appointment at Montreal and went to Philadelphia.

In 1889 he was appointed to the Johns Hopkins Hospital, he visited Europe once more in the following year and in 1891 he commenced his *magnum opus* which appeared in 1892. The Medical School of the Johns Hopkins University was opened in 1893. In February 1900 he was virtually offered the vacant chair of Professor of Medicine at Edinburgh; this after much hesitation he very reluctantly refused. In 1904 he accepted the Regius Professorship at Oxford which he held until his death.

He married in 1892. His son, Revere, was born in 1896 and was killed in France in August 1917. He was

made a baronet in 1911 and died at Oxford on December 29th, 1919.

Sir William was not only a great physician, probably the greatest of his day, but a writer of considerable merit and one of the wisest advisers of his day on practical affairs of all sorts.

As the writer of the "Life of Sir William Osler" says, little pretence has been made to do much more than let his story tell itself as far as possible through what he has put on paper. It is the simple story of a great man well told.

MEDICINE MONOGRAPHS, VOL. IV, CALORIMETRY IN MEDICINE.—By William S. McCann. Baltimore: Williams and Wilkins Co., 1924. English Agents, Messrs. Baillière, Tindall & Cox: London. Pp. 98. Price, 11s. 6d. net.

THE author deserves the thanks of the profession for bringing out this practical book on calorimetry, a science which has made so much progress during the past few years. A working knowledge of calorimetry and its practical application to every-day problems in the diagnosis and treatment of diseases, especially those of the ductless glands, for example Grave's disease, or of metabolic diseases like diabetes, are essential now-a-days for the scientific and successful practice of medicine.

The author discusses the subject of basal metabolism, giving normal standards for adults and children and in pregnancy also. He then goes on to discuss the importance of determination of the basal metabolic rate in various diseases (thyroid disease, fever, anæmias and lukæmias and other miscellaneous pathological conditions).

The action of the thyroid extracts, of epinephrin, insulin, pituitary extracts, of the many antipyretics and some of the more important alkaloids and other drugs on the basal metabolic rate is ably discussed in the book and will amply repay perusal.

We recommend this useful book to practising physicians who will find it helpful in dealing with such diseases as hypothyroidism, malnutrition, anæmia, obesity, fevers, cardiac and nephritic diseases.

MEDICINE MONOGRAPHS, VOL. V, DYSPNŒA.—By James Howard Means. Baltimore: Williams and Wilkins Company, 1924. English Agents, Baillière, Tindall & Cox, London. Pp. x plus 108, with 22 figs. Price, 11s. 6d. net.

THE significance of dyspnœa, its bearing on the diagnosis, treatment and prognosis of many diseases, the detailed analysis of the physiological causes giving rise to this important symptom are all of considerable value in practical medicine, and the physician would be lacking in his duty to the patient, if he does not try by all the methods of observation open to him to elicit the true cause underlying this distressing symptom. The author has carefully interpreted the latest facts which have been brought to light during the past few years and has attempted to scrutinize the various important factors, structural and functional, which directly or indirectly play a part in the production of this symptom.

The author has ably discussed the subject in relation to:—

- (a) dyspnœa associated primarily with increased metabolism,
- (b) dyspnœa associated primarily with disturbance of acid base equilibrium,
- (c) dyspnœa associated primarily with difficulty in oxygen transport,
- (d) dyspnœa associated with mechanical and nervous hindrances to the respiratory movements,
- (e) cardiac dyspnœa, and
- (f) the dyspnœa of pneumonía.

We feel sure that this book will be of great value to all students of medicine.

THE DIABETIC LIFE—ITS CONTROL BY DIET AND INSULIN.—By R. D. Lawrence, M.A., M.D. London: J. & A. Churchill, 1925. Pp. 161, with 10 illustrations. Price, 7s. 6d. net.

THE author's object in writing this little book is to furnish to general practitioners and patients (whose co-operation is essential in the successful treatment of diabetes) certain useful information regarding the modern treatment of diabetes by diet and insulin. He lays down a few simple rules of treatment which it would profit the busy general practitioner to remember and to follow, and by which an intelligent patient would benefit himself and help his doctor considerably by following the simple rules laid down for him.

The "Line-ration" scheme of dieting which the author has devised is ingenious and quite simple to follow; it is likely to help an intelligent patient to select a suitable diet for himself according to his own habits and taste.

We have no doubt that the book will prove helpful to both doctors and patients.

BUCHANAN'S MANUAL OF ANATOMY, INCLUDING EMBRYOLOGY.—Edited by E. Barclay-Smith, M.D., J. E. Frazer, F.R.C.S., F. G. Parsons, F.R.C.S., and W. Wright, F.R.C.S. Fifth Edition. London: Baillière, Tindall & Cox, 1925. Pp. 1702, with 810 illustrations, mostly in original and in colours. Price, 35s. net.

THE last edition, which appeared six years ago, was to all intents and purposes a reprint of the preceding edition. The present edition has been revised and considerable portions of the previous text have been rewritten. The general arrangement of the work has however not been substantially altered. Many new illustrations have been incorporated. The illustrations, though perhaps missing the artistic excellence of those to which we were accustomed in the older editions, are very clear, sufficient and self explanatory.

Since it deals with anatomy regionally the work must appeal especially to the student, whilst an excellent index enhances its value from the point of view of those who wish to use it as a work of reference.

The practical guide to dissection has been omitted from this edition and will be published as a separate volume.

Perhaps the greatest change is in the section dealing with embryology, with which the book commences in a chapter outlining the elements of the subject. A description of the development of the various organs is given in greater detail under their appropriate headings; the descriptions are full enough but not tediously long, in short they are just what the student requires and no more.

Last but not least the old terminology is adhered to.

We consider the work a very sound investment for the student.

SCHISTOSOMIASIS VEL BILHARZIASIS.—By C. G. Kay Sharp, M.D., with a foreword by J. B. Christopherson, C.M.G., M.D., F.R.C.P., F.R.C.S. London: John Bale, Sons and Danielsson, Ltd., 1925. Pp. 74. Price, 7s. 6d. net.

THIS is a useful little treatise on schistosomiasis as it occurs in Natal and Zululand, for medical practitioners and educationists who have to deal with the problem. Dr. Sharp gained his experience of the disease in the schools of Natal, and as most of the cases are first contracted in childhood the school offers one of the best means of investigating the disease, and the best field for a fight against it. In his foreword Dr. Christopherson places the prophylactic measures in the following order: (1) mass treatments in schools and villages, and treatment of individual cases wherever encountered, (2) educational propaganda to check infection and re-infection, and (3) destruction of snails in local infected collections of water.

Dr. Kay gives a brief historical résumé, after which he deals with the etiology, pathology, incidence, diagnosis, treatment and prevention of the disease. In one Indian school in Natal 40 out of 300 children were passing ova in the urine. In Durban schools 3.4 per

cent. of the male children are infected, on the basis of recorded cases only. Native women are much less affected than the men owing to their not bathing in public bodies of water. In his recommendations for prevention of spread of the disease Dr. Sharp urges that notification of schistosomiasis be made compulsory, and that free treatment be provided for. In Natal the prognosis is good, and deaths certified as being due to schistosomiasis are rare. The last chapter gives a review of the literature on treatment of African forms of schistosomiasis.

HAND-ATLAS OF CLINICAL ANATOMY.—By A. C. Eycleshymer, B.S., Ph.D., M.D., and Tom Jones, B.F.A. London: Henry Kimpton, 1925. Pp. 424, with 395 line drawings, mostly in colour. Price, 50s.

THIS almost sumptuous work is in every way admirable. It is the outgrowth of a special *Manual of Surgical Anatomy* prepared during the War for officers in the Medical Corps of the U. S. A. Army and Navy. The original edition of 3,000 copies was soon extended to 10,000 copies and even this failed to meet the demand. In the present atlas the anatomy of the female has been included, and some 107 new drawings added. The authors are respectively Director of Anatomy and Director of Anatomical Illustration in the University of Illinois.

The four sections of the book deal with the head and neck; the thorax, abdomen and pelvis; the upper extremity; and the lower extremity. The illustrations are, as far as possible, so arranged as to present (a) transparencies—in which are viewed the various deeper structures in their natural positions as though the overlying structures were transparent; (b) systematic dissections; (c) regional dissections; (d) sections, shewing the relationship of structures in sagittal, frontal and transverse sections; whilst finally (e) a special section deals with surgical incisions, shewing the typical incisions and the more common sites of surgical attack. A series of drawings of muscle projections, shewing the muscles in relation to body outline and bony structure, is an original and most valuable part feature of the book.

The illustrations are almost all in colour, are admirably clear and well executed. Conciseness, regional arrangement and quick adaptability for the surgeon's needs are special features of the book. A very complete explanatory index renders a descriptive text unnecessary, and facilitates quick reference.

We have nothing but praise for this very ably executed work. It should be in the hands of every anatomist and surgeon.

THE CRIPPLED HAND AND ARM.—By Carl Beck, M.D. London: J. B. Lippincott Co. Pp. 243, with 302 illustrations. Price, 30s. net. Obtainable in India from Messrs. Butterworth & Co. (India), Ltd., P. O. Box 251, Calcutta. Price, Rs. 22-8.

AS the title suggests, though written primarily for the surgical specialist, this work is well worth including in the library of the general practitioner, since, as the author points out, the patient's chances of regaining the usefulness of the damaged member are directly influenced by the first treatment meted out to him by the general practitioner, to whom in the first instance these injuries are brought.

It is a remarkable book, and contains a wealth of technical detail and clinical illustration; if one may make a criticism it would be to suggest that the work would have been even more valuable had the author placed the discussion of general principles more clearly in the foreground, and used his clinical material to illustrate the principles as they were enunciated. As the work stands one is a little in danger of losing sight of the forest from the multitude of the trees.

From the point of view of the surgeon in this country the section of the book dealing with the crippling of the hand by burns will be found the most useful; probably in no country in the world are more grievous

deformities of the hand and arm met with due to this cause than in India.

The section relating to disabilities and crippling due to mutilation emphasises the importance of preserving every scrap of tissue which will survive for the subsequent scheme of reconstruction; even the smallest fragment of a phalanx may add to the usefulness of the remodelled hand.

The section on technique, which might with advantage be expanded, draws attention to the usefulness of the sliding flap, and to its great superiority over the Wolff graft or the Thiersch graft. Some very ingenious methods of reconstructing tendons are given in this portion of the work.

In the chapter dealing with the hand crippled from birth there is related a really remarkable construction of a useful hand from an inert stump, and in a subsequent chapter the account of a reconstruction as remarkable from the stump of a hand crippled from injury.

For Dupuytren's contracture the author recommends the radical procedure of excising the whole of the skin covering the palm of the hand and replacing it with a pedicled flap. The remedy is heroic but in common with many heroic remedies is probably more satisfactory than a number of half-hearted and partial measures in the long run.

We can cordially recommend the work to anyone whose practice brings him many of these cases of mutilation and deformity to treat.

PITFALLS OF SURGERY, SECOND EDITION.—By Harold Burrows. London: Baillière, Tindall & Cox. Pp. x plus 525. Price, 12s. 6d. net.

THE first edition of this book was published in 1922, and was the subject of a good deal of comment. It fell into the hands of the lay press and somewhat sensational copy was extracted. The title of this book has been altered to the above.

As the author puts it—"Attention has been given only to actual occurrences, on the simple and sure ground that what has happened once may come about again." The book cannot fail to be of interest to the surgeon, and also of value, in that he can find here a multitude of mistakes which have actually occurred to others. One sees here mistakes in diagnosis emphasised, which one meets with in the practice of surgery, but which one never finds mentioned in the ordinary literature. The book is especially useful to the beginner. For example, the author gives a long list, which in the nature of things must be incomplete, of diseases which have been diagnosed and operated on for appendicitis. To the beginner some of these will be new, the man of experience could add to them. Much advice of great value is to be found. The book should find a place in every surgeon's library.

There is one serious publisher's error, viz., from page 481 onwards the pages are misplaced, e.g., after 481 comes page 500, then page 497 and so on. Seven or eight pages are missing. In fact from page 481 to 513 it is impossible to understand the text as the sequence is lost.

LISTER AND THE LIGATURE.—Compiled by the research readers of the Scientific Department of Johnson and Johnson, New Brunswick, N. J., U. S. A. Pp. 94. Illustrated.

THE authors of this little book state that, having lived through the years covering the re-introduction and re-birth of surgical ligatures and sutures, they have put together the story of this, one of the very greatest of events in the progress of surgery.

The first portion of the book covers briefly the period before Lister. Ligatures—even catgut ligatures—were no new story, even in ancient surgery. From time to time they would be introduced; but as their use was invariably attended with sepsis and severe secondary hæmorrhage, their use would die away again for a time until they were re-introduced, again as a novelty.

Lister's introduction of antiseptic—later of aseptic—surgery, however, revolutionised the position; and here, in the main portion of the book, the authors have collected together a most valuable compilation of Lister's publications on the subject together with a full bibliography. Many of Lister's original papers are now inaccessible, and in thus presenting them collected together, the authors carry out a valuable service to the surgeon and to the student of medical history.

Lister's original drawings are reproduced, and the illustrations also include a portrait of Lord Lister, a picture of his famous carbolic spray apparatus, and of the Lister medallion in Westminster Abbey.

This book cannot compare with Sir Rickman Godlee's immortal study of Lord Lister; but it is a useful and valuable publication.

THE SCIENTIFIC AND OTHER PAPERS OF RAI CHUNILAL BOSE BAHADUR, C.I.E., I.S.O., M.B., F.C.S. VOL. II.—Edited by J. P. Bose, M.B., F.C.S., Calcutta School of Tropical Medicine. Pp. 558. Price, Rs. 5.

THE first volume of these collected papers was reviewed in our issue for October, 1924. The papers in the second volume deal with many important subjects; with hygiene and public health; the temperance question; biographical sketches; popular scientific lectures; and social problems. Together they form an important, non-technical and thoughtful contribution to many of the most important public health and social questions of the day in India.

A reprint from the *Calcutta Medical Journal* of 1910 deals with the measures necessary for the prevention of food adulteration, an exceedingly important problem in India. An essay on common Indian foodstuffs is followed by an admirable one on practical hints for the improvement of the dietary of Bengalis; this last indeed is a chapter which should be read by all medical men practising in Bengal. The milk supply of Calcutta is dealt with frankly and with no attempt to minimise the dangers from dishonest *gowallahs* and conditions of sale;—on the whole it may be said that some 40 per cent. of all samples analysed from various sources were found to be adulterated. It is indeed largely owing to the advocacy of Rai Bahadur Chunilal Bose as Chairman of the Calcutta Municipality that legislation has been introduced in the recent Municipal Act to improve what was a shocking state of affairs. Further, a standard of purity for Indian milk supplies is suggested in detail for buffalo's milk which the public health worker will find interesting and of important practical value.

In dealing with Indian infant mortality, the author pleads for improved sanitary conditions in lying-in rooms and for the employment of skilled help during labour, whilst maternity and child-welfare schemes for Calcutta are outlined, one of which at least is now in being. The health of Bengali college students—a most important racial question—is fully dealt with. The drink and drug traffic is dealt with forcibly and from the point of view of the future of the temperance movement in India.

In the biographical sketches Dr. Bose deals with such well known pioneers as Sir Jagadis Bose, and Dr. Mahendra Lal Sircar, the founder of the Indian Science Association. Finally a series of popular lectures on scientific subjects is followed by a series of most important papers on social questions in Bengal. The author condemns wholeheartedly the imposition of enormous marriage dowries on the marriage of Bengali girls; he advocates raising of the general age at marriage, the greater extension of marriage between subsections of the same caste, and the curbing of extravagance in expenditure on marriages. Professional beggary in Calcutta and the Calcutta Suppression of Immoral Traffic Bill of 1923 are also social matters dealt with.

The book is full of interest, not only to the educated medical man of Indian nationality, but also to the European reader. It presents the mature views and opinions

of a brilliant and widely educated Indian savant and thinker, thoroughly familiar with the many and important questions with which he deals, free from prejudice, but filled with ambition for the betterment of the condition of the people. Its informative value is very great.

PUBLIC HEALTH LABORATORY WORK (CHEMISTRY).—By H. R. Kenwood, C.M.G., M.B., D.P.H., F.R.S., F.C.S. Eighth Edition. London: H. K. Lewis & Co., Ltd., 1925. Pp. xii plus 369. Price, 12s. 6d. net.

It is difficult to include all the subject-matter on public health chemistry within a small compass, as the scope of the subject is very big. The author is to be congratulated on having presented this very successfully in his treatise to students of public health chemistry in a very clear and simple manner. Within the narrow limit of 363 pages he has left few points untouched. We can safely recommend this as a text-book on public health chemistry to the student going up for the D. P. H. examination of the Calcutta or other Indian university.

Nearly the whole of public health chemistry has been dealt with in one handy volume. The fact that the book had to be edited for the eighth time in the course of five years since its publication in 1920 is a proof of its growing popularity among public health students and public health workers. The present edition is an improvement on the last one; although the number of pages is diminished, the subject-matter remains the same. The old edition has been fully revised. The chapter on soils has been omitted, and at the end "The British Admiralty Test and Physical Test for disinfectants" which is entirely a new subject has been inserted.

We wish that some mention had been made of the subject of hydrogen ion concentration which has of late found so wide an application in public health chemistry. This could have been very easily included in Chapter XVI on "Acidimetry and Alkalimetry." Part I, on water. The "scheme for the detection of poisons added to water" given on p. 128 might preferably have been included in the chapter on poisonous metals on p. 40. The subject of poisonous metals added to water, e.g., barium, oxalic acid, mercury, potassium cyanide and strychnine, is more a medico-legal or forensic subject than akin to public health chemistry. A very short note on softening processes would not have been out of place in the chapter on hardness of water.

In connection with estimation of fat in milk one is disappointed not to find any mention of Gottlieb Rose's method which is the only method applicable to sour milk, and also of Leffmann-Beam's original process.

Diagrams illustrating Kjeldahl's process for estimation of nitrogen and Polenske's modification of Reichert-Meissl's process would have been very much welcomed by the student in India, also the description of the *Lancet* baryta-acetone method, which seems to be the standard method for the chemical analysis of phenolic disinfectants, would have been much appreciated by them.

With the above exceptions which are of course of only minor importance, the book practically satisfies the needs of public health students as well as of the public health worker.

B. B. K.

THE PATHOLOGY OF TUMOURS.—By E. H. Kettle, M.D., B.S. (Lond.). Second Edition. London: H. K. Lewis & Co., 1925. Pp. viii plus 284, with 159 illustrations. Price, 12s. 6d. net.

The second edition of this excellent manual is a welcome appearance.

The first section, which is concerned with the general biology of tumours, contains new material, particularly in that portion of it which deals with the experimental study of cancer.

The section on the endotheliomata presents the situation with regard to these tumours in a well considered manner.

It should help those who consult it to make fewer diagnoses of endothelioma, for, as stated on p. 169, "there has been far too great a tendency to name any unrecognised or anomalous tumour an endothelioma."

The controversy concerning the hypernephromata is outlined in some detail; that concerning the melanomata is brief and non-committal. Part III gives a concise description of the occurrence of tumours in special regions of the body.

The book is well produced and illustrated, there being many new figures, while "most of the original photographs of naked eye specimens have been replaced by drawings."

It is a worthy addition to the library of laboratory workers and teachers as well as students.

HANDBOOK OF GYNÆCOLOGY.—By Bethel Solomons, B.A., M.D. Second Edition. London: Baillière, Tindall & Cox, 1925. Pp. xlv plus 303, with 217 figs. and 2 coloured plates. Price, 12s. net.

We are glad to welcome the second edition of Dr. Bethel Solomons' "*Handbook of Gynæcology*."

The first edition was published in 1919 for the express purpose of providing a small, concise handbook for the medical student, and it has filled a long-felt want, for many of the text-books on gynæcology are now extremely bulky. In the second edition of Dr. Solomons' little book, about 50 pages of subject-matter have been added, also two coloured plates, and several extra drawings. The author has considerably lengthened the chapter on sterility, and special mention is made of a modification of Rubin's method of demonstrating the patency of the Fallopian tubes, which is as excellent as it is simple.

The notes on endometritis, erosion, dysmenorrhœa, and secondary amenorrhœa have also been greatly added to, and some mention is made of endocrine therapy in the last-named condition.

The last chapter in the book is an excellent contribution by Dr. Walter Stevenson on the use of x-rays and radium in gynæcology, and is a very welcome addition.

We can recommend this little book to the medical student, when beginning the study of gynæcology.

DISEASES OF THE EYE. A MANUAL FOR PRACTITIONERS.—By Lieutenant-Colonel H. Kirkpatrick, I.M.S. (retd.). Calcutta: Butterworth & Co., 1925. Pp. 132, with 28 half-tone illustrations. Price, Rs. 6-8 net.

This small book from the well-known pen of Colonel Kirkpatrick is one which will fill a gap between the teaching of the ordinary text-book and the actual facts of practice as found in India. It is described as an attempt to help practitioners in remote parts to render serviceable first-aid in eye cases, but in reality its detailed clinical differentiation of the common eye conditions and suggestions for treatment will be found useful by those with considerable experience. It is a purely clinical handbook and the ordinary detailed anatomy and pathology of the text-books is largely omitted, as well as all description of the rarer diseases not likely to be met with, and methods of examination such as tonometry not available to the ordinary practitioner. On the other hand the only ophthalmoscope described is the electrical self-lit one now available in cheap forms, (and no one who has experience with it will ever use any other), and the same touch of modern thought and practice extends through the whole book.

The first 22 pages of the book are devoted to the diseases of the lids and conjunctiva, considerable stress being laid on the differentiation between trachoma and the many conditions frequently mistaken for it, and their treatment being well given; 17 pages are given to the diseases of the cornea and lachrymal passages, non-ulcerative keratitis is well described, and the conditions resembling trachoma pannus but due to other irritations are clearly indicated.

In dealing with ulcerative conditions associated with infections of the conjunctiva, the open treatment and use of the author's magnesium sulphate lotion is advised. Diseases of the iris and ciliary body are discussed very briefly in 7 pages. In these first three sections the rôle of leprosy in attacking the eye is well pointed out.

Glaucoma is also treated very briefly, but the differential diagnosis of its acute and chronic forms is well and simply explained, and this section should be of great service to any practitioner when confronted with a puzzling case.

Eleven pages are devoted to cataract, the ordinary types and their causes being briefly described, while the questions of diagnosis, maturity, and the treatment of traumatic cases are discussed in some detail.

Disturbances of the motility of the ocular muscles are described in 9 pages, and this is probably the poorest part of the book, as it is impossible to do justice to this complicated subject in so short a space.

Examination of the fundus is described in 12 pages; this section is very good, as is also the description of how to use the ophthalmoscope. The account of the commoner morbid conditions seen with it is very simple and clear, and stress is laid on the recognition of retinal arterio-sclerosis which is of so much importance.

Eye strain, and the correction of errors of refraction occupy 9 pages, the 'fogging' method being described in some detail, but it is strange to find in the short description of retinoscopy that the necessity for a mydriatic when using this method is not mentioned.

Fifteen pages are devoted to operations on the eye. This section is well written, only the most usual and satisfactory operations being described, and the descriptions are very clear and adequate.

The last few pages are devoted to a number of useful prescriptions for various conditions.

The general get-up of the book is good and the illustrations are clear and useful.

In conclusion we may say that we know of no better elementary text-book for use in Indian medical schools, if it be combined with systematic oral teaching in elementary anatomy and pathology, and we can recommend it to all general practitioners as a valuable addition to their libraries, even if they already possess one of the larger systematic text-books.

Correspondence.

WANTED, SCORPIONS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I should feel much obliged if any of your readers can recommend to me any method of catching scorpions, or of attracting them in large numbers by artificial means. I desire to extract oil from them, and accordingly require scorpions in thousands.—Yours, etc.,

H. B. TEJUMAL,
Medical Practitioner.

CHIPRI QUARTERS, NEW SUKKUR, SIND.

7th November 1925.

[Note.—We have no doubt that if suitable financial inducement were offered, scorpions could be had in the requisite thousands. At least we recollect one enterprising snake-catcher who went in for breeding cobras when monetary rewards were offered for a supply of these snakes for venom-collecting purposes. Possibly however some of our readers may know sufficient of the domestic habits of the scorpion to give Dr. Tejumal the required information.—EDITOR, I.M.G.]

THE DANGERS OF DUSTING POWDERS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the correspondence section of your issue for July, 1925, a letter appears from Mr. S. D. Narain, under the title "A case for Diagnosis."

Mr. Narain has unfortunately omitted to tell your readers what the dusting powder he was using in this case consisted of. If it was the common "B. & I." (boracic acid and iodoform) powder, then I think that the solution is perfectly simple and the diagnosis iodoform poisoning. The conditions in a post-burn ulcer are more favourable for the rapid absorption of iodoform than in a non-burn ulcer, for obvious reasons, and one must always bear this in mind, apart from the question of personal susceptibility, idiosyncrasy, etc.

I consider that in place of treatment with digitalis and strychnine in the case, sedative measures should have been employed together with direct antidotes, such as intravenous injection of one pint of 2 per cent sodium bicarbonate solution, repeated if necessary. I remember a similar case in my own experience which occurred at the Remount Depot, Mona in 1909, where similar symptoms set in owing to the excessive enthusiasm of the out-patients' departmental dresser. Under the above treatment the patient made a complete recovery in 48 hours.

There is no question of uræmia here, especially as Mr. Narain failed to detect any albumin in the urine.—Yours, etc.,

B. J. BOUCHÉ,
Assistant Surgeon, I.M.D.

JUTOGH, SIMLA HILLS,
16th August 1925.

GLYCOSURIA IN LEPROSY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Since 1918 I have observed that in almost all cases of leprosy, even before the disease manifests itself either as the nodular or the nervous variety, the urine is able to reduce Fehling's solution, and shews the characteristic glycosuric reaction, although not as strongly as is observed in cases of diabetes.

The reaction continues during the course of the disease. Have any of your readers had any similar experience; and if so, is there any relationship between leprosy and glycosuria? I have searched many text-books, but have not been able to find any mention of glycosuria in leprosy.—Yours, etc.,

P. S. SRINIVASAN, L.M.P.

CONJEEVARAM, S. INDIA,
4th November 1925.

[Note.—We have shewn the above to Dr. Muir, Leprosy Research Worker at the Calcutta School of Tropical Medicine, who remarks that frequent examinations of the urine have been carried out at the Gobra Leper Asylum, Calcutta, but glycosuria has not been found to be a frequent affection in leprosy cases.—EDITOR, I.M.G.]

"PYREXIA OF UNCERTAIN ORIGIN."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have recently come across two similar cases of pyrexia, and would like to invite opinion as to the correct diagnosis in these cases.

The patient gets a sudden chill, followed by fever rising to 103° F., which then drops to normal, with sweating. The febrile period occupies about eight hours. This intermittent fever lasts for about 4 days, but the chills become less severe, and the temperature now becomes remittent, with no chill and no sweating. The remittent fever is followed by intermittent lysis, the morning temperature becoming sub-normal.

The course of the fever occupies 14 days, and the patient's chief complaint is of excessive pain and aching all over the body, especially in the abdomen, and of headache. The tongue is clean or only very slightly coated. The patient is constipated to begin with, but an enema acts well. The pulse rate never exceeds 90 per minute. In one of the cases there was slight bronchitis, in the other some pharyngitis. The muscles of the body are tender to pressure all over.

The first of these cases—a boy of 19—was taken to be malaria, then typhoid fever, then appendicitis, etc. Quinine in full doses had no effect upon the temperature and increased the pains. I was consulted on the 6th day of illness and gave urotropine, grs. 30 daily together with a mixture containing a drachm of ammoniated tincture of valerian, 10 minims of tincture of belladonna and grs. 15 of sodium bicarbonate. The patient did very well on this line of treatment, although morphia, administered to relieve the pain, had only a temporary effect.

The second case was that of a Brahmin female patient, aged 25. I was consulted on the 4th day of illness. The pain increased during the febrile attacks, but persisted during the apyrexial periods. The same treatment seemed successful in her case also.—Yours, etc.,

K. M. SHENAI, L.M. & S.

CAR STREET, MANGALORE,
2nd December 1925.

BACK VOLUMES OF THE "INDIAN MEDICAL GAZETTE."

MAJOR H. STOTT, I.M.S., Dean of the Faculty of Medicine, Lucknow University, King George's Medical College, Lucknow, has appealed to us to ask whether any of our readers can supply him on payment with volumes of the *Indian Medical Gazette* for the years 1865 to 1880, 1885, 1886 and 1887, which are wanted for the library of the University. The publishers of the *Gazette* have no copies of these volumes in hand, but possibly some of our readers may be able to supply Major Stott with them.—Editor, *I.M.G.*

THE WILLIAM GIBSON RESEARCH SCHOLARSHIP FOR MEDICAL WOMEN, ROYAL SOCIETY OF MEDICINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Miss Maud Margaret Gibson has placed in the hands of the Royal Society of Medicine a sum of money sufficient to provide a Scholarship of the yearly value of £292, in memory of her father, the late Mr. William Gibson, of Melbourne, Australia. The Scholarship is awarded from time to time by the Society to qualified medical women who are subjects of the British Empire; and is tenable for a period of two years, but may in special circumstances be extended to a third year. The next award will be made in June, 1925.

In choosing a Scholar, the Society will be guided in its choice "either by research work already done by her, or by research work which she contemplates. The scholar shall be free to travel at her own will for the purpose of the research she has undertaken."

There is no competitive examination, nor need a thesis or other work for publication or otherwise, be submitted. The Society has power at any time to terminate the grant if it has reason to be dissatisfied with the work or conduct of the Scholar.

Applications should be accompanied by a statement of professional training, degrees or diplomas, and of appointments, together with a schedule of the proposed research. Applications must be accompanied by testimonials, one as to academic or professional status, and one as to general character. Envelopes containing applications, etc., should be marked on the top left-hand corner "William Gibson Research Scholarship" and should be addressed to Mr. G. R. Edwards, Secretary, Royal Society of Medicine, 1, Wimpole Street, London, W.1., and be received not later than Tuesday, June 1st, 1926.—Yours, etc.,

G. R. EDWARDS,

Secretary, Royal Society of Medicine.

1, WIMPOLE STREET,
LONDON, W.1.,
(Received: 11th January 1926.)

Service Notes.

APPOINTMENTS AND TRANSFERS.

In supersession of previous orders, the services of Lieutenant-Colonel W. F. Harvey, C.I.E., I.M.S., Director, Central Research Institute, Kasauli, are placed at the disposal of the Director-General, Indian Medical Service, with effect from the 4th June 1925, and he is granted, preparatory to retirement, leave on average pay for 8 months combined with leave on half average pay for 20 months, with effect from the same date.

Lieutenant-Colonel S. R. Christophers, C.I.E., I.M.S., is confirmed as Director, Central Research Institute, Kasauli, with effect from the 24th June 1925.

Lieutenant-Colonel W. G. Hamilton, I.M.S., is confirmed as Inspector-General of Prisons, Bengal, with effect from the 19th October 1925, *vice* Lieutenant-Colonel F. S. C. Thompson, O.B.E., I.M.S., retired.

The services of Major J. B. Hanafin, C.I.E., F.R.C.S.I., I.M.S., Officiating Director of Public Health, Assam, are placed temporarily at the disposal of the Government of Bombay with effect from the date on which he is relieved of his present duties.

Major N. S. Simpson, I.M.S., Superintendent of the Presidency Jail, is appointed to act as Inspector-General of Prisons, Bengal, during the absence, on leave, of Lieutenant-Colonel W. G. Hamilton, I.M.S., or until further orders.

Captain G. B. Hanna, I.M.S., Superintendent of the Dacca Central Jail, is appointed to act as Superintendent of the Presidency Jail, *vice* Major N. S. Simpson, I.M.S., appointed to act as Inspector-General of Prisons, Bengal, or until further orders.

Captain B. H. Singh, M.C., I.M.S., officiating Civil Surgeon, Midnapore, is appointed to act as Resident Medical Officer, Medical College Hospitals, Calcutta, *vice* Major N. C. Kapur, I.M.S., granted leave.

LEAVE.

Lieutenant-Colonel W. G. Hamilton, I.M.S., officiating Inspector-General of Prisons, Bengal, is allowed leave for seven months and eight days on average pay, with effect from the 13th December 1925, or any subsequent date on which he may avail himself of it.

Major N. C. Kapur, I.M.S., Resident Medical Officer, Medical College Hospitals, Calcutta, is allowed combined leave for one year, with effect from the 1st January 1926, or from any subsequent date on which he may avail himself of the leave.

PROMOTIONS.

The undermentioned Majors (now Lieutenant-Colonels) Indian Medical Service, are granted the acting rank of Lieutenant-Colonel whilst employed with the Mesopotamian Expeditionary Force:—

(1) G. Browne, D.S.O., M.D., from 9th August 1914 to 15th January 1917.

(2) A. B. Fry, C.I.E., D.S.O., M.D., from 1st December 1916 to 27th January 1919.

(3) L. Reynolds, M.B., from 22nd December 1916 to 12th October 1917.

(4) W. R. Battye, D.S.O., M.B., F.R.C.S., from 26th June 1917 to 27th January 1918.

Subject to His Majesty's approval, the promotion of Major S. Gordon, M.C., M.B., I.M.S., to the rank of Major is post-dated from 27th to 29th July 1924.

RETIREMENT.

The King has approved the retirement from service of Lieutenant-Colonel F. S. C. Thompson, O.B.E., M.B., I.M.S., with effect from the 19th October 1925.

RELINQUISHMENT OF RANK.

Captain (Actg. Major) (now Major) J. G. B. Shand, I.M.S., relinquishes the acting rank of Major on ceasing to be employed with a Casualty Clearing Station, 7th April 1919.

NOTES.

'ARTIFICIAL SUNLIGHT.'

At present heliotherapy—the treatment of disease by exposure of the body to intense sunlight—is undergoing a boom in the lay press. We are treated to pictures—more or less badly reproduced—of rows of patients in delightful open air hospitals in the Alps, reverting to a state of nature, and bathed in radiant heat. In a recent and very clever short story in *Punch*, a tired millionaire is advised to undergo such treatment in the most deserted spot which he can find in the Pyrenees. He does so, and his nostalgia disappears from him “as doth a garment.” His discovery, however, that the fashionable mother and daughter from whom he has expressly fled, and who are the *bête noire* of his existence, are also undergoing the same treatment on the other side of the same hill, causes a severe relapse of his former condition, and he commits suicide!

It is well that the public should take an intelligent interest in the doings of the medical profession, but sensationalism is to be profoundly deplored, and it behoves all concerned to maintain a rational point of view. Heliotherapy, and actinotherapy—the term used to describe all forms of treatment by artificial ultra-violet radiation, are still in their infancy. Dr. Rollier, who is generally regarded as the greatest living authority on treatment by natural sunlight, states “Sun- and ultra-violet rays bear much the same relation to one another as crude drugs to their synthetically prepared chemical substitutes.”

The use of sunlight is crude and is beset with many difficulties; that of artificial ultra-violet rays can be standardised, controlled, and made available at any time. The action of the rays has been shewn by Browning and Russ to vary from those in the near ultra-violet region of the spectrum, which have great powers of penetrating the skin, but little germicidal value; to those in the far ultra-violet region, which are strongly germicidal, but have little penetrating value.

In their recent bulletin on “Artificial Sunlight,” Messrs. Watson & Sons (Electro-Medical), Ltd., Sunic House, 43, Parker Street, Kingsway, London, W. C. 2. deal with the apparatus used for all forms of ultra-violet or photo-therapy. The brochure illustrates no less than 17 distinct models. Among lamps for general treatment the mercury vapour lamp is perhaps that in most general use; and here their artificial Mountain Sun atmospheric mercury vapour lamp is of interest. The radiations from the tungsten arc, however, are remarkably uniform and have advantages over the mercury vapour lamp both with regard to uniformity and intensity throughout the whole therapeutic range of the spectrum, and the best model for the general practitioner, who is bent on securing the widest possible scope of utility with a single installation, is probably the lamp with carbons cored with molybdeno-tungsten powder, shewn on p. 17 of the brochure.

For local applications the tungsten “Hall lamp” and “Premier lamp” are illustrated, whilst there are also fittings enabling the “Artificial Mountain Sun mercury vapour lamp” to be used for this purpose.

Messrs. Watson's pamphlet will undoubtedly interest all medical men who have taken up the study of the subject. They express it as their decided view that, whilst research work must be left to those competent to carry it out, and whilst sensationalism in the lay press and elsewhere should be steadily combated, it is their duty as manufacturers of experience and standing to see to it that their apparatus shall embody suitability and reliability, and shall incorporate the latest results.

CONTREXEVILLE MINERAL WATER.

The spa treatment of gout, rheumatism, and many different types of synovitis and arthritis by mineral

waters is a sensible and rational proceeding,—one far better in procedure and often far better in results than the attempt to use injections of potent drugs which may do harm rather than good. Among such spa treatments in Europe the reputation of the Contrexeville spring stands very high, the patient not being drugged, but instructed with regard to his diet and habits, and made to contract a new habit, that of drinking the water daily. The English agents for the Contrexeville-Pavilion Mineral Water are Messrs. L. Guggenheim, 36, Mark Lane, London, E. C. 3; and the Indian agents; Messrs. Kemp & Co., Charni Road, Queen's Road, Bombay.

“PHARMASOLS.”

THE use of colloidal solutions in medicine is daily increasing and it is important for the practitioner to have such solutions of a truly colloidal, and not merely suspensory character, and of reliability. With regard to both requirements the “Pharmasols” of the Anglo-French Drug Co. (Eastern), Yusuf Building, Church Gate Street, Bombay, offer attractive products. Amongst the various “Pharmasols” listed are “Pharmasol” antimony for use as a substitute for other antimony preparations in leishmaniasis; “Pharmasol” argentum, for use in chronic inflammations of mucous membranes; “Pharmasol” arsenicum for intramuscular injection of arsenic in anæmias and skin diseases; “Pharmasol” bismuthum for oral use as a very fine preparation in dyspepsia and gastritis; “Pharmasol” collo-calcium in tuberculosis; “Pharmasol” iodum for use wherever iodine is indicated; and, of special interest, “Pharmasol” chaalmoogra oil, either as a 1 per cent. preparation for oral use to provide the leper patient with a palatable and easily taken preparation for oral use in place of crude and nauseating chaalmoogra oil, or in sterile 0.1 per cent. solution for subcutaneous and intravenous administration.

SRINIVASAN'S MEDICAL DIARY FOR 1926.

THIS is the second year in which we have had the pleasure of receiving this useful little handbook for review. It is published by V. Srinivasan, 44, Rattan Bazaar Road, Madras, at the price of Re. 1 and contains information of special value to medical men in India. The usual information as to pharmacopœial preparations, posology, weights and measures, etc., is followed by a list of new and non-official remedies with their synonyms. A list of drugs used in S. India gives their corresponding names in four vernaculars. Obstetric, ophthalmological and other information and tables are followed by medico-legal information under the Madras laws. The calendar itself gives all the (numerous) Indian festivals and holidays in S. India, and one full blank page for every day of the year. Finally the calendar is cheap, of handy size and well bound. We regret that it was received (in December) too late for notice in our issue for last month, but would like to bring its annual existence to the notice of our readers.

MESSRS. G. W. CARNRICK CO.'S NEW PRICE LIST.

WE have received from Messrs. G. W. Carnrick Co., of New York, a copy of their new price list for September 1925; which shews mainly reductions in the price of preparations of desiccated single glands. Messrs. G. W. Carnrick Co.'s glandular preparations are well known, and cover a very wide range of endocrine products, both from mixed and from single glands. “Hormotone,” “Hormotone without post-pituitary,” and “Secretogen” are perhaps the best known products of this firm. In all cases the dosage given is in terms of the desiccated gland product, as is required in the U. S. A. and British Pharmacopœias. The Indian agents are Messrs. Muller and Phipps (India), Ltd.

ALVARENGA PRIZE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about three hundred dollars, will be made on July 14, 1926, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published. The essay should represent an addition to the knowledge and understanding of the subject, based either upon original or literary research. They must be typewritten, and in English acceptable for publication without necessity for editing by the Committee. Any illustrations should be appropriate and correctly annotated with the text. Essays must be received by the Secretary of the College on or before May 1, 1926.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1925 has been awarded to Dr. Raphael Isaacs, Boston, Massachusetts for his essay entitled:—"On the nature of the action of Roentgen Rays on living tissue."

JOHN H. GIRVIN, *Secretary*,
19, South 22nd Street, Philadelphia, Pa, U. S. A.

MESSRS. NEWTON AND WRIGHT'S RADIATION AND DIATHERMY APPARATUS.

We have received from Messrs. Newton and Wright, 471 1/3, Hornsey Road, London, N.19, brochures dealing with apparatus which they have recently designed or improved from older models for ultra-violet therapy and diathermy. Their "K. B. B. Atmospheric Quartz Burner" for ultra-violet therapy is of special interest in that the quartz envelope is not exhausted, but works under atmospheric pressure. Vacuum seals can therefore be dispensed with; the burner is of robust construction, and in a recent test one of them ran for 9,000 hours before it failed. Of mercury vapour arcs for full body treatment, a complete model of sun type, mounted on a floor stand with fittings is listed at £45, also a cheaper one for suspension from the ceiling at £20-10-0. For the treatment of restricted areas their "K. B. B. type A, medical lamp" with water cooled housing and quartz window, fitted for wall insertion, costs £55-7-0. A "Universal table," 1925 model, has many features of interest. In their "Holway" diathermy apparatus, suitable either for hospital practice or for surgical purposes, special attention has been paid to the spark-gap. This consists of an aluminium chamber extensively ribbed on the outside, so that even with a large current it does not become unduly hot. This chamber is provided with an inlet and an outlet tap for gas dielectric, and can also be arranged for use with ether in cases where no gas supply is available. The actual gap comprises a large copper disc, heavily silvered, bridging over the space between a pair of heavy copper electrodes, likewise silvered, so that the gap is in duplicate, an arrangement which conduces to a steady current, while affording means of convenient and delicate adjustment. The electrodes, which are mounted on thick mica diaphragms, are provided with radiation fins for cooling.

Other interesting equipment described is a new "Holway" Potter Buckley diaphragm, which can be used in the upright position in conjunction with a suitable screening stand, or used inverted over the table with

the tube below the table; also their "Instanta Flexible" intensifying screens.

HORLICK'S MALTED MILK CO.'S 1926 CALENDAR.

We have received from Messrs. D. J. Keymer and Co. (Horlick's Malted Milk Co.), a copy of their most sumptuously coloured calendar for 1926, which we think will especially appeal to medical men in India, since its subject is chess in an Indian zenana. In describing the calendar, Messrs. Keymer writes:—

"Three of the chess verses of Khayyam are illustrated in the setting of the game and the general surroundings, and are printed at the foot in the Naskhi character. One, transliterated in Roman as well, is the origin of Fitzgerald's famous paraphrase:—'Tis all a Chequer board of Nights and Days."

This will be of interest to many readers who have never seen Omar in the original dress. All who read Urdu can follow the easy Persian.

A special and interesting feature is the exact reproduction on the zenana panels of two pages of the beautiful *nim-shikasta* MSS. on which Fitzgerald's *Rubaiyat* is mainly based.

The calendar will, we think, be best appreciated in Turkey, Persia, Iraq, all Urdu-speaking or Urdu-reading Northern India, and in States or other circles of the South where Persian or Urdu is read.

It may at first sight appear that, apart from the heading, there is very little matter in the calendar as propaganda for Horlick's, but this has been left to suggestion. Horlick's Malted Milk is being quietly prepared by a female attendant on the left just under a verse expressing a craving for wine—Omar's weakness, if we take him literally.

A verse ascribes the lady player's victory to a complexion out-rivalling the eglantine or Chinese fairest porcelain idols, and as she is evidently a votary of Horlick's, the readers will give H.M.M. the credit for her good looks. Nor will they fail to notice that two glasses of Horlick's are being prepared, and conclude from the virility and physical fitness of the Prince that, notwithstanding his Khayyamesque pose and surroundings, he has long since made up his mind about his favourite beverage."

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

DIFFERENTIAL DIAGNOSIS IN THE TROPICS.*

By A. H. PROCTOR, M.B., B.S., M.D., M.S.,

LIEUT.-COLONEL, I.M.S.,

Civil Surgeon, Darjeeling.

RECENTLY one of my colleagues made a remark that diagnosis in this country was very different to what it is at Home. What in England was a perfectly straightforward case of say appendicitis, had in Calcutta all kinds of possibilities.

I propose therefore to set out some of my own experiences in the hope that they may be of use to practitioners and help them to avoid mistakes which I and others have made.

The subject is a little difficult to arrange, and after consideration I have decided to take up the ordinary tropical diseases and describe cases in which they have simulated other diseases. An alternative method would have been to take up certain symptoms and describe the diseases likely to give rise to them. This is the method usually followed in books on differential diagnosis such as French's invaluable "Index." In this case I feel it would not emphasise the object I have in view, namely, the many protean manifestations of some common tropical diseases.

To begin with we must concede first place to *malaria*. This table gives the symptoms originally complained of in 426 cases admitted to hospital.

Usual symptoms	362
Anæmia	4
Vomiting	7
Gastric pain	6
Colic	2
Hæmatemesis	3
Diarrhœa and dysentery	11
Cholera	1
Difficulty of micturition	3
Respiratory conditions	12
Collapse	3
Typhoid state	1
Cerebral and nervous symptoms	7
Jaundice	4
			426

I want you to bear in mind that the diagnosis of malaria was only arrived at after a stay in hospital, and that, originally, all that these cases complained of were the symptoms

* Being a clinical post-graduate lecture, delivered at the Calcutta School of Tropical Medicine.

recorded. Of course under the head "vomiting" we have only included cases where vomiting was the sole symptom complained of. It is scarcely necessary to state that vomiting accompanied by fever, ague, etc., is one of the commonest symptoms. Such cases have been included in the 362 usual signs and symptoms.

Figures are dull and I do not propose to discuss percentages or anything of that sort. The table is only put forward to illustrate the numerous disguises under which malaria presents itself in your consulting room. I was surprised myself to see how seldom vomiting appears in the table. My own experience is that patients frequently come to see you and their first reply to your question is "I can't keep anything in my stomach." As often as not when questioned they will say they have no fever. Especially with mothers who bring their children. Nowadays in the case of children who are vomiting one immediately examines their urine for acetone and diacetic acid, finds them present and promptly makes a diagnosis of acidosis. Blessed word! It has got the doctor out of many a tight corner with a persistent mother. But it won't save your reputation with her if after a course of alkalis someone else examines the blood and finds malarial parasites. So I advise you in every case of vomiting to have a blood film taken. Even if you cannot get a blood film never fail to examine the spleen, it is nearly always palpable.

Here is the type of case described as gastric:—

Complains that for the last month he has had neuralgic pains from the back of the neck to the shoulder-blade and then to the stomach. Pain settled in the pit of the stomach, felt like something pulling him crossways, intermittent, not severe enough to double him up. Has never vomited blood, no tarry stools, no relation with food—(note that point),—but could not retain anything for more than 20 minutes, icteric tinge to conjunctiva, stools always bilious and urine high-coloured. Mustard plaster relieves his pain. Temperature 97.6°, pulse 96, no anæmia; tenderness on deep pressure 1" below the xiphisternum. No mass felt. Note how up to this point the recorder's mind has run on duodenal or gastric ulcer; none of his enquiries suggest a suspicion of malaria. He then continues, "Spleen slightly enlarged, liver normal, not tender." Three days later malignant tertian rings and crescents are found, the patient is put on quinine and discharged cured, but from the date of admission to discharge he never has a rise of temperature. Had it not been for his blood examination he might still have been on bismuth and gastric sedatives. He had been on them for the best part of a month before admission, and was probably described as a gastric type of influenza. The notes do not

record his diagnosis prior to admission to hospital.

Numerous cases of this type come under observation and I can only conclude that the pain is splenic in origin. We know little at present as to the cause of pain in the abdominal viscera, but it is easy to suppose that with an enlarged and engorged spleen, pain may well be referred to areas associated with the stomach. While on the subject of pain due to affections of the spleen, it occasionally happens that it is referred to the left shoulder; much as liver pain is referred to the right. I have seen this happen in a case of kala-azar, a disease we do not usually associate with pain.

Of colic two cases are recorded. These were intestinal colic associated with fever. The most striking case however was one of renal colic. As Medical Officer of the Officers' Hospital in Mesopotamia I was sent for to see a case of renal colic. The attack was typical in every way of renal calculus. It followed on a hard game at tennis and was accompanied by a transient hæmaturia and moderate rise of temperature. Under the usual treatment the patient was better in the morning. The next evening he had another attack with the same result. When a third attack occurred at the same time the following evening we decided it was time to take a blood film. The result was positive and on quinine his renal colic disappeared and as far as I know never returned.

The result was dramatic in its sudden termination. The pathology I have no doubt was a blocking of the renal capillaries by parasites, and hæmorrhage, resulting as it usually does in marked renal colic, owing to the passage of clots.

Let us now turn to the cerebral and nervous types of malaria. My attention was first drawn to the possibilities of error many years ago in China. I have not the notes of the case with me now, but it so impressed itself on my memory that I can quote them fairly accurately.

He was a Punjabi recruit only recently arrived and was brought to hospital with a story that he had wakened up that morning paralysed in both legs. On examination he had no temperature but symptoms of a complete transverse myelitis. He said he was quite well the evening before. In hospital that evening he had a temperature and developed retention of urine and some extension of his paralysis. A consultation of the medical officers of the hospital carried us no nearer the solution, and as there was no malaria at that time among the troops we did not suspect it. A tertian periodicity in his temperature suggested an examination of his blood and malarial parasites were found. He made a perfect recovery on quinine. Apparently he

had contracted malaria in the Punjab before sailing and developed this unusual nervous type immediately on arrival. I can assure you I had considered the possibility of several nervous diseases, but malaria had not crossed my mind. So far as I remember I was in favour of an acute anterior poliomyelitis. We are all acquainted with the ordinary cerebral type of malaria, but it is as well to bear in mind that almost any abnormal nervous symptoms may be due to malaria, more especially if accompanied by fever, and that treatment is urgent if the patient is to be saved. Thus we may meet with coma, convulsions, apoplexy, aphasia, paraplegia and meningeal cases. Convulsions and meningeal types are particularly common in children.

Neuralgia, more especially supra-orbital neuralgia, is stated to be commonly associated with malaria, but in my experience it is a rare complication or sequela. I should hesitate to attribute even a supra-orbital neuralgia to malaria till I had exhausted all the more probable causes such as carious teeth, nasal sinus affections, ophthalmic affections, and syphilis.

The presence of loose stools and the passage of blood and mucus in the stools sometimes leads to an erroneous diagnosis when it is due to malaria, the blood being attributed to dysentery or to hæmorrhage in a case of typhoid. Perhaps the most difficult cases are the algid type, of which you will see one which is described as cholera and the others as collapse. These are not common, but when they are first seen mimic the collapse stage of cholera very closely and I have known them treated as cholera. An examination of the blood and stools usually clears up the point, but as one's attention is usually concentrated on giving hypertonic saline and not on laboratory examinations it is useful to remember that the intravenous injection in cases of cholera usually results in the passage of typical cholera stools and fresh vomiting. This is not the case in malaria, nor does the case improve to the same extent with the injection.

Of jaundice it may be said that a mild icteric tinge is an almost universal accompaniment of malaria, but that occasionally one sees cases of deep jaundice, of malarial origin. Jaundice in these cases is due to excessive destruction of blood cells and whether this is due to an increased fragility of the red cells due to prophylactic quinine or other causes, or whether a severe infection plus damage to the polygonal cells of the liver, I do not know. Certainly the jaundice does not always seem proportional to the severity of infection and therefore we may conclude that some secondary factor is included as well.

Finally the most likely cases to be overlooked are those of general debility and *malaise*. Frequently a patient consults you who does

not feel well but can tell you nothing definite. A week or two later he has a typical attack of malaria and the reason for his *malaise* becomes obvious. In these cases an examination of the blood when the patient is first seen often reveals malarial parasites. They are important cases to recognise because they are easily cured when diagnosed.

So far I have said little as to the actual differential diagnosis. The table I have shown only gives conditions that are due at times to malaria and have been labelled as other than malaria. If I were to attempt to describe all the conditions that I have seen labelled malaria I should practically cover every disease accompanied by fever, or an enlarged spleen. My object has been rather to describe those conditions due to malaria, liable on superficial examination to have a more obvious diagnosis made. How are we to avoid mistakes in atypical cases? First and foremost of course an examination of the blood. The finding of malarial parasites gives you a confidence and certainty in diagnosis and treatment that nothing else can. Unfortunately in this series of cases parasites were only found in 41 per cent. of the cases. This seems a low figure at first sight but I believe it must be about the average for hospital statistics. The unusual cases I have cited were diagnosed because parasites were found and it is chiefly in typical clinical cases that we have to record a failure to find the parasite. This is due to several causes but the commonest is undoubtedly the result of a dose or two of quinine before admission. What other guide have we then in doubtful cases? Colonel Calvert used to teach that the quinine test was more reliable than the microscope, and Rogers is more definite still. He states, "The longest period I have known a fever, showing malarial parasites in the blood, to last under efficient quinine treatment is six days. Even in this case marked benefit was obvious on the fifth day." He also states the average duration of fever for malignant tertian cases to be 2.1 days and of benign tertian infections 1.57 days. Only 8 per cent. of malignant tertian cases lasted more than four days. So that if quinine is properly administered a fever lasting more than four days is not malarial. Yet we frequently have cases admitted as malaria who have had fever treated for weeks with quinine without any result. I ask you to note Rogers' qualification, "under efficient quinine treatment." The important points in that are adequate dosage, a soluble quinine product, and a preliminary mercurial purge.

The only trap I know of in the quinine test is the terminal rise of dengue. Cases coming in on the 6th or 7th day with a history of several days' fever, chill and high temperature on the day of admission, may be given

quinine and are normal next day. In this case a very slow pulse in proportion to temperature is in favour of dengue, plus the acute back-ache and enlarged cervical glands. The remaining characteristic feature of malaria is the slight icteric tinge combined with anæmia, which gives a characteristic look to malarial cases in Europeans, and is particularly valuable in patients complaining of debility.

Let us now leave malaria and turn to its greatest rival in this part of the world, *kala-azar*.

Kala-azar 150 Cases. Primary Symptoms.

Fever and enlarged spleen	..	120
Do. and anæmia	..	7
Ascites	..	4
Genito-urinary	..	2
Diarrhoea and dysentery	..	5
Enlarged liver and jaundice	..	1
Cancrum oris	..	2
Joint pains	..	1
Nervous symptoms	..	2
Lung conditions	..	3
Vomiting	..	3

Total .. 150

In this table you see that most of the atypical conditions complained of are recognised complications of *kala-azar*, and it is chiefly with the differential diagnosis of the fever we are concerned.

By far the commonest mistake is to diagnose *kala-azar* as enteric fever. No less than 31 of the 150 cases had the initial fever diagnosed as enteric, many of them in hospital. Now that I am alive to the possibility, I am more suspicious, and in Calcutta I am inclined to regard continued fevers as *kala-azar* until Widal reactions and cultures prove that they are enteric. There are one or two points of value however in differentiating the two. Firstly, the spleen steadily enlarges with the duration of the fever in *kala-azar* and as a rule it reaches a larger size than it does in enteric. Secondly, the general condition of the patient is, as a rule, less toxic than the duration of the fever would lead you to expect. Thirdly, there is a progressive leucopenia, so that the proportion of white cells to red cells falls below 1 in 1,000. Fourthly, the double rise in 24 hours. We seem now however to be getting a much more acute type of *kala-azar* than formerly, and latterly I have found the less toxic condition of cases not such a safe guide. The leucopenia and double rise are the main points on which to rely. Jaundice is also frequent in these acute cases, and marked flatulent distension, so marked indeed that it masks both spleen and liver. I used to regard a hæmorrhage from the bowel as confirmatory of enteric but this is not so. It seems to be almost as common in *kala-azar*.

I recently diagnosed septic cholangitis in a case which ultimately proved to be kala-azar. The patient was an old gentleman suffering from diabetes who developed fever with chills and profuse sweats, fairly deep jaundice, marked distension of the bowels and an enlarged and tender liver. There was no marked leucopenia, his white cell count being 6,000 and his red cells 4,200,000. His spleen was not palpable till the 30th day of his fever. On the strength of an increasing leucopenia and a double rise on one occasion we punctured his liver and found Leishman-Donovan bodies. He responded rapidly to treatment with stibamine.

Shortly after, an almost similar case came in although his spleen was markedly enlarged. In this case a liver puncture was negative but he was given von Heyden "471" and his temperature fell shortly after, and on "471" the patient is improving steadily. I think that in "471" and urea stibamine we have a therapeutic test of considerable value. Dr. Napier informs me that he considers the therapeutic test takes too long to be of value and, because of the dangers associated with the administration of antimony, does not agree on this point. I agree with him if sodium antimony tartrate is used, but not in the case of the organic antimony compounds recently introduced.

I must admit that examination of the peripheral blood has failed me and I have little experience of blood cultures, though they would appear to be the easiest and simplest solution of the difficulty. I am chary of splenic punctures unless the spleen is enlarged to a considerable extent and in such cases it would seem hardly necessary. In children a general anæsthetic is essential to carry out a spleen puncture safely.

After enteric, considering the rarity of the disease, malignant endocarditis is the commonest disease to mistake for kala-azar. Of course the cardiac murmurs should put you on your guard, but often these cases give a history of long-standing heart disease and in such cases, in Calcutta, you regard the case as one of kala-azar arising in a case of chronic heart disease. The blood count is a help of course but often fails, as do blood cultures. The main safeguard however is to be aware of the possibility of the two diseases being mistaken for each other. The spleen of malignant endocarditis is usually tender and undergoes sudden painful enlargements due to embolism. The golden rule never to explain symptoms as arising from two diseases when they can be accounted for by one, will save many an error.

The tendency to hæmorrhage characteristic of kala-azar gives rise to errors, and I have had several cases of fever plus hæmoptysis due to

the Leishman-Donovan body. The natural inclination is to diagnose such cases as tuberculosis with slight physical signs, unless a very thorough examination is made.

The first case of kala-azar I had shown to me in a *mofussil* hospital proved to be a case of splenomedullary leukæmia. Of course an examination of the blood at once revealed the true nature of the disease. As cases frequently have pyrexia for prolonged periods the mistake was not an unnatural one in a hospital which, at that time, did not possess a microscope. Once again I would emphasise the necessity of using your microscope.

It has always seemed curious to me that in a country where pathological conditions of the spleen are common, we scarcely ever hear of splenomegaly due to conditions which prevail in Europe. I refer to splenic anæmia, acholuric jaundice and syphilitic disease of the spleen in infants, to say nothing of the rarer Gaucher's spleen and von Jaksh's disease.*

With regard to splenic anæmia and acholuric jaundice, splenectomy is the recognised treatment and is followed by good results. It is therefore important to recognise the condition. These conditions are not so very uncommon, as I saw during my last furlough two cases of acholuric jaundice and one of splenic anæmia in the neighbourhood where I was living, though the population of the area cannot have been more than 2,000.

The probability is I think that in this country these cases are attributed to more common causes of splenomegaly and are therefore overlooked. I myself have not seen any cases but it is only recently I have been on the look out for them.

It would seem improbable that a case of malaria should be diagnosed as kala-azar, but such a case was admitted last year who had had a course of injections for kala-azar until he was too weak to attend for more. He was very weak and emaciated on admission and had an enlarged spleen but no enlargement of the liver. Blood examination showed a benign tertian infection and he rapidly improved on quinine. There is such a condition as malarial cachexia and it is an unfortunate error to diagnose it as kala-azar.

Jaundice without fever is sometimes caused by kala-azar. A useful point in these cases is the fact that bile remains present in the stools, distinguishing it from obstructive jaundice. Sooner or later fever appears.

Let us now turn our attention to infections by *Entamæba histolytica*.

* But see the article by Capt. W. C. Spackman on Gaucher's type of splenomegaly in a Mahratta village. *Indian Med. Gaz.*, Feb. 1925, 69—Editor, I.M.G.

You will see quite a large number of cases came in complaining of alternating diarrhoea and constipation. This is very usual, so usual that I doubt if I should comment on it, except that patients often attribute the diarrhoea to the preceding constipation. Constipation is also frequently troublesome after an attack of dysentery. In all such cases the stools should be emulsified and carefully examined. It is not of much use to look at a stool, it must be broken up and emulsified thoroughly. Often both blood and mucus will then be found when they would have been missed in an ordinary stool. Major Hingston, I.M.S., demonstrated to me a most excellent way of obtaining samples of mucus when looking for the amoeba in acute and subacute cases of dysentery. He inserts a gum elastic Coudé catheter in the rectum, turns it round several times, withdraws it and then takes a specimen of the mucus contained in the eye of the catheter. In this way absolutely fresh specimens are obtained and the entamæba and other parasites shown in full activity. It saves waiting for a stool and ensures a fresh specimen.

Difficulty of micturition in the shape of stranguary is so urgent and trying that the patient forgets to mention his having dysentery.

It is usually associated with ulceration of the rectum. Appendicitis and dysentery are so frequently confused, and the need for accurate diagnosis so urgent, that I have learnt to regard a diagnosis of appendicitis as to say the least difficult. There is of course no reason why a dysenteric ulcer should not arise in the appendix and in such cases you would have a true inflammation of the appendix and it would require surgical treatment just as much as any other. Why do I say the need for accurate diagnosis is urgent? Well, appendicitis we all regard nowadays as an acute abdominal emergency requiring immediate operation, but if by mistake you submit a case of acute dysentery to operation you will find such cases have a very high mortality. They stand operation badly. The mistake will be avoided if a careful history is obtained, remembering that constipation is usual in appendicitis, that the onset is fairly sudden, and previous attacks the rule. McBurney's point is very definite and localised; it is not a vague ill-defined area in the iliac fossa. It is in fact no longer as a rule than the tip of your forefinger. Also remember Murphy's rule that the order in which symptoms appear in appendicitis is pain, nausea or vomiting, local sensitiveness, then temperature and leucocytosis. Any variation in this order should make you suspicious, and bear in mind that the pain of the first few hours is referred to the umbilicus. In dysentery careful enquiry will probably reveal some diarrhoea, an absence of nausea and an early elevation of temperature. Tenderness is not localised but fairly general over the cæcum and colon. While we are on the subject of appendicitis, once again a tropical disease, namely, dengue, results in an exception to the rule pain, nausea, local tenderness and fever. Appendicitis appears to be frequent in cases of dengue, in which case, of course, the temperature rises early. The association of dengue and appendicitis would seem worth investigating.

The appendix in its turn may be the cause of dysenteric symptoms. Thus an appendix abscess in the pelvis will cause frequent stools containing mucus, tenesmus and pain and it is by no means uncommon to see such cases regarded as dysentery until a mass appears above the pubis. Pelvic abscesses due to other causes produce similar symptoms. The ulcerative conditions of the rectum are frequently diagnosed as dysentery, amoebic or bacillary, and I would warn you against the tragic mistake of diagnosing carcinoma of the rectum as a chronic dysentery. Always make a rectal examination in a case of blood or mucus in the stools which fails to improve rapidly under treatment. Amoebic conditions improve so rapidly under emetine and stovarsol that there is no excuse for cases continuing for weeks, without a rectal examination,

but, in my own experience, I have known such a case treated as dysentery until secondary deposits in the liver revealed the correct diagnosis. At the opposite end of the scale I have known a case of amœbic ulceration of the rectum treated for two years as "piles." In both cases they had never had a rectal examination. No case should be diagnosed as chronic dysentery unless a careful examination of the stool has revealed the organisms known to cause dysentery. I have not diagnosed a case of dysentery as intestinal obstruction, but I must own up to having lost much valuable time in diagnosing an acute intussusception in an infant as a bacillary dysentery. The large quantity of blood and mucus passed mimicked a bacillary dysentery stool very accurately, and the usual tumour was difficult to feel and then only resembled the thickened colon so common in dysentery. Eight hours later the diagnosis was clear. Perhaps I was influenced by the fact that on a previous occasion on which I saw a laparotomy done for intussusception, the case proved to be one of dysentery.

When we come to amœbic infections elsewhere than in the intestine, the commonest organ involved is the liver. Of the 33 cases you will see that more than half presented unusual features. The peritonitis cases were ruptured liver abscesses, the lung affections basal pneumonias or ruptured abscesses. Fever alone is not uncommon and it was Rogers who first drew attention to the pre-suppurative stage of hepatitis. The effect of emetine is probably the most useful test for it, as it usually markedly influences the temperature in three days. It is, however, useful to remember that quite large liver abscesses may remain latent and produce no obvious symptoms till they rupture into the lung or abdominal cavity.

If they rupture into the lung they are liable, if small, to be mistaken for lobar pneumonia. Once again a microscopic examination of the sputum furnishes the diagnosis and results in a dramatic recovery under treatment.

If they rupture into the abdomen the usual diagnosis is a ruptured gastric or duodenal ulcer. These are most often abscesses of the left lobe which at all times are difficult to identify.

Undoubtedly the greatest aid to the diagnosis of hepatitis and liver abscess is an x-ray screen examination. The radiologist can in these cases almost invariably give you a positive or negative diagnosis.

One point that suggests an amœbic infection is the peculiar earthy complexion such cases get and the doughy inelastic skin.

While the liver and intestines are the commonest sites of amœbic infections, other tissues of the body are liable to infection. Ulcers of the skin have been described and

abscesses of deep muscles are occasionally met with.

By far the most tragic case in the Calcutta General Hospital records was a cerebral abscess which on post-mortem examination proved to be a pure amœbic abscess. When one thinks what emetine could have done for such a case one cannot help feeling guilty at not attaching importance to a history of dysentery some time before. The *Entamoeba gingivalis* is found in the gums. Major Knowles, I believe, considers it harmless, but I have seen a spongy hæmorrhagic condition of the gums clear up wonderfully on emetine administration. A variety of conditions of the gums are common in India, not all of them ordinary pyorrhœa. If spirochætes are present, as they frequently are, a course of arsenic will frequently clear up the whole condition.

Cancrum oris, we frequently see in kala-azar, but I do not think it is generally realised how easily it can be stopped in the initial stages. An inspection of the mouth should be part of the routine daily examination of kala-azar cases.

In the early stages of cancrum oris there will be found a thin grey line of ulceration along the margin of the gum in contact with the teeth, slight salivation and a somewhat foul breath. If this is treated with carbolic acid and spirit, it usually clears up and the whole process is checked, if left a few days we have a typical cancrum oris case.

In conclusion, I would draw attention to some of the results of treatment. Quinine is responsible for many cases. It is taken over long periods in the malarial districts and accounts for much indigestion and many gastric troubles. Apart from noises in the ears, vertigo, etc., which are well known, a common symptom is tachycardia. Sudden attacks of faintness, and syncope may be found to be entirely due to quinine, and not to debility following malaria, the fact being proved by stopping quinine when the attacks rapidly clear up. I also think that anæmia is sometimes due to quinine but that is difficult to prove.

Of course when we come to deal with intramuscular injections of quinine we find all sorts of disasters arising. I may say that nothing would induce me to have an intramuscular injection of quinine. There is, to my mind, no doubt that in this country tetanus has followed the most careful administration of quinine intramuscularly. I have seen a number of abscesses result from it.

Secondary hæmorrhage into the site of the injection happened in one case. It was incised as an abscess and it was only by direct transfusion after a series of hæmorrhages that the boy's life was saved. Sciatica is by no means uncommon, but the most disastrous nerve complication I have seen was a complete musculospiral paralysis following an injection

into the triceps. He was an Indian Army cavalry officer and of course had to be invalided out of the service.

Emetine also produces occasional abscesses and tachycardia, and I saw one case many years ago of peripheral neuritis which I attributed to emetine.

Now that arsenic is being so much more extensively used, I expect we shall see more cases of exfoliative dermatitis. I saw a case before the Standing Medical Board of extensive peripheral neuritis resulting in complete paralysis of the lower limbs. This was admittedly due to a course of soamin. He had then been 21 months on leave and could only walk with difficulty.

The title of this lecture is "Differential Diagnosis in the Tropics," but I seem to have said little on that subject and a good deal on other subjects. I may therefore fitly conclude by returning to the subject of the lecture. There is no royal road to accurate diagnosis, but the simplest and straightest is to recognise and profit by your mistakes. Be honest with yourself, even if there are times when you have to be discreet with friends and relatives. Professor Drummond urged that a post-mortem should be compulsory before a death certificate was granted. He stated that most death certificates were inaccurate in stating the cause of death. At any rate when you do not know the cause of death it is a good thing to try and get a post-mortem.

What are the main points to attend to in diagnosis? First and foremost, an accurate history of the present and previous illness. I have already alluded to this in differentiating between dysentery and appendicitis, but I think if you recall the case of cerebral abscess due to *Entamoeba histolytica* you will appreciate the value of an accurate history.

Secondly, get into a habit of using a microscope. This is so obvious that it would seem unnecessary to mention it, yet cases are sent over and over again to hospital, after treatment outside, without ever having had blood smears or stools examined.

While you have spare time, use it yourself and don't fall back on laboratories which do this work for a fee. If your patient can afford it, get these laboratories to confirm your findings or to rectify your own personal errors, but don't come to rely entirely on them. You may find yourself in a place where it would take days to get a reply. If you are going a long way to see a case and are not likely to see the case again take your microscope with you.

As an example of the use of the microscope:—

A small boy was brought to see me. His mother stated that for some time he had had occasional hæmorrhages from the bowel. I

asked many questions and eventually on the history given came provisionally to the conclusion that probably the cause of the hæmorrhage was a polypus of the rectum. There was no history of diarrhoea. I passed a catheter into the rectum—however—and examined the undoubted blood I found in the eye when I withdrew it under the microscope. I found *Entamoeba histolytica* in large numbers and no further examination was necessary to clear up the diagnosis.

Thirdly, a careful physical examination when the case is first seen. Your first examination is always the most careful. After a week or two you suffer from what Professor Wilkie has described as clinical staleness, and fail to go over parts you have already examined. Some men are immune to this staleness, but very few.

In the temperate zone it is usual to begin from above downwards and starting from the head go to the chest. In the tropics I think it is best to begin on the abdomen and come to that when fresh, and then proceed to other areas. The order in which you examine the organs is immaterial but it is best to follow the same routine. I usually take the spleen, liver, gall bladder, stomach and pylorus and then the appendix region and colon.

In all fevers a four-hourly chart is essential. In several cases the double rise in 24 hours has suggested kala-azar before any other signs. A culture of the blood and of the urine will often enable you to make an early diagnosis of enteric, kala-azar or bacilluria.

The physical examination is not complete without an examination of the stools and of the urine.

Fourthly, a knowledge of the geographical distribution of disease is of great value. Thus we know that the prevalent long-continued fever of Bengal is kala-azar, but in the Punjab it is more likely to be enteric or Malta fever. A bubo in the Punjab suggests plague, in Bengal we need scarcely consider it and our prognosis is considerably altered.

In the hills, relapsing fever is common in the cold weather. In lower Bengal it is almost unknown. In Scinde and Bagdad chronic sores are usually due to Leishmania infection, not so in this part of India.

In the tea-garden areas anasarca is commonly due to *Ankylostoma* infection, in Calcutta to nephritis, beriberi, or epidemic dropsy.

Lastly, to bear in mind that many tropical diseases present themselves in atypical forms which mimic other diseases. I have endeavoured here to draw attention to some of these atypical forms, but the subject is so vast that I should perhaps have been better advised to restrict myself to one disease.

At a later date I hope to discuss some of the other tropical diseases such as ankylostomiasis,

leprosy, schistosomiasis, relapsing fever, rat-bite fever and rarer conditions.

I also desire to acknowledge the help of Dr. C. C. Mitra in preparing the tables in this article.

ONE SEASON OF ANTI-MALARIAL WORK AT PASIGHAT.

By P. N. MITRA, M.B., D.T.M. (Bengal),

CAPTAIN, I.M.S.,

Pasighat, Assam.

PASIGHAT is the headquarters of the subdivision of the same name within the district of Sadiya Frontier Tract in Assam. This district was formerly known as the North East Frontier District, which name gives a rough idea as to its geographical position. It is situated at the foot of the Abor Hills, on the right bank of a river of considerable size—the Dihang. The soil is sandy and porous and though the rainfall is heavy and there are a few pools and puddles, very little anopheles breeding occurs in these. Running parallel to the Dihang at a distance of about half a mile from it is a small stream called the Mora-Lalli, which is formed by the junction of about a dozen springs cropping up at the foot of a low hill range. Pasighat was originally founded by clearing the bank of the Dihang river of virgin jungle for a distance of about $\frac{1}{2} \times \frac{1}{4}$ mile. In 1915 certain parts of the banks of the Mora-Lalli were cleared of jungle for the first time for agricultural purposes. Since then jungle clearings have been and are being systematically extended, and at the present moment nearly a mile of the Mora-Lalli is clear of jungle, except at its sources where some large trees are still standing.

From 1912 to 1915 there was nothing noteworthy about the incidence of malaria in the station. Malaria was noticed to be bad at Pasighat in 1916. It became worse in 1917 and at the request of the executive authorities the Sanitary Commissioner of the province came down to investigate the matter. In January 1918 he diagnosed the disease to be malaria, identified the anophelines responsible and incriminated the Mora-Lalli to be their breeding place. He recommended, among other measures, oiling the stream, clearing the station of jungle from the Dihang to the Mora-Lalli, filling in of puddles and pools and the prophylactic issue of mosquito-nets and quinine where practicable. The anophelines identified by him were the following:—*A. maculatus*, *sinensis*, *fuliginosus*, *barbirostris*, *aikeni*, *neo-aikeni*, *listoni* and *culiciformis*. Of these *A. maculatus* predominated. For some obscure reason the task of oiling was left to a non-medical department, the officers of which had no training for this sort of work. They were using a mixture of crude and refined kerosene oils which was poured into kerosene oil tins with a hole knocked

at the bottom and fitted with a gauze wick. These wicks lost their capillarity in a short time and then acted as plugs, preventing any dripping. In addition the actual breeding places were not found out and dealt with.

In February 1925, Major D. L. Graham, O.B.E., the civil surgeon of the district, visited the station and made certain recommendations. A fresh anopheline survey was carried out. Except a very few *A. listoni*, only *A. maculatus* was detected (kindly identified by Capt. Barraud). The seepage areas at the source of the Mora-Lalli were dealt with by contour drainage and these new drains were treated, with oil putting into them perforated cigarette tins into which a handful of rag soaked in kerosene oil had been put. Practically no breeding occurred in these new drains. Breeding, however, was detected in the stream about $\frac{1}{2}$ mile from its source where it runs through grassy meadow. In this part the edges of the stream were hand weeded and sprayed with kerosene oil with the help of a garden syringe. The number of drip-cans was also increased. Two other temporary breeding places were also discovered and dealt with. Breeding was found going on in exposed springs in the bed of the Dihang river in October. This too was dealt with by oiling. The drip-cans were improved by substituting small stopcocks for gauze wicks.

The position as regards malaria is shown in the charts.

Oiling however is only palliative. Further, with increased jungle clearing the breeding ground of *A. maculatus* is likely to increase as the larvae of this species require open and clear spring water. The history of the station also points the same way. Clearing on the banks of Mora-Lalli first began in 1915 and malaria became bad at Pasighat for the first time in 1916. On account of expense the idea of putting the stream under-ground cannot be considered at present. But it is possible

that if further deforestation be stopped on the banks of the stream and the part of the stream already exposed by deforestation be permitted to relapse into jungle, in time

also to various officers of the medical and political departments, without whose co-operation this work would not have been possible.

Postscript.—Oiling was continued from April to October, each year, but in 1925 it was found that *A. maculatus* was breeding in the Mora-Lalli in November. So in future oiling should be continued till the end of November at least.

THE TREATMENT OF LACERATED WOUNDS WITHIN TWO HOURS.

By R. J. L. SLADEN, F.R.C.S., D.P.H.,
District Surgeon, G. I. P. Railway, Jhansi.

WOUNDS, usually of a lacerated nature, must necessarily be of frequent occurrence in a hospital for railway staff. From an economical point of view, it is of great importance that they should be dealt with as rapidly and efficiently as possible, so as to prevent (as far as can be arranged for) a permanently disabled condition and to return the sufferers back to duty as soon as possible.

Experience during the war demonstrated the great importance of getting them treated as soon after infliction as circumstances admitted. Within two hours it is possible so to disinfect a wound that it may heal by first intention and some of the best results were obtained by adopting the so-called B. I. P. P. treatment. After treating some cases by this method in Jhansi, and seeing an extraordinary and fortunate result in the hospital of my colleague Dr. Ambler in Bombay, a circular was issued advising its adoption in all the hospitals on the G. I. P. Railway in 1923 on the following lines:—

- (1) To stop all hæmorrhage.
- (2) Place a sterilised swab over the wound.
- (3) After thoroughly washing the hands with hot water, soap and nail brush for not less than 5 minutes, wash the surrounding skin for at least 18 inches around the wound with the same.

- (4) Wash the wound in every crevice with hot water and soap.

Nos. (3) and (4) are procedures which may be left out unless the wound is very dirty.

- (5) Cut away loose tags of muscles and skin with sterilised scissors and forceps.

- (6) Wash every crevice with spirit applied with a sterilised swab.

- (7) Paste every portion of the wound with B. I. P. P., applied with a sterilised swab, taking care to leave very little in the depth of the wound.

- (8) Sew the wound up. Apply tincture of iodine and dress with dry sterilised gauze or lint.

the Mora-Lalli may become unfit for *A. maculatus* breeding. Oiling of course, to be continued till then. It should be noted that *A. umbrosus* was never found here. I invite criticism from those who know on this point.

My thanks are due to Major D. L. Graham, O.B.E., and Mr. T. P. O'Callaghan, the civil surgeon and political officer of the district respectively, for constant advice and encouragement,

(9) An anæsthetic is nearly always necessary.

(10) There is frequently a rise of temperature which does not necessarily indicate that the wound is not doing well.

(11) The dressings may be left on up to a week if there is no local pain, but should be otherwise removed sooner. There is no harm in daily dressing provided the wound is kept dry and sterilised dressings applied. When re-dressing, keep the wound dry, use friars' balsam, tincture of iodine or methylated spirit.

(12) B. I. P. P. consists of:—

Liquid paraffin	..	1 oz.
Bismuth subnitrate	..	1 oz.
Iodoform	..	2 ozs.

(13) Iodoform poisoning might possibly occur, but has been most unusual.

The details of treatment were thus defined. To begin with in many cases, especially where medical subordinates did not realise how impossible it is to thoroughly clean a wound without an anæsthetic, the results were not ideal, but in spite of this it seems to have been a definite step in the right direction and materially shortened the time of healing, and I have not yet heard of a method that has produced as good results.

Writing in 1914, Russell Howard says, when there is much laceration of the wound, especially when dirt is ground into it making it almost impossible to render it surgically clean, the wound should not be closed immediately. The part should be fomented with some antiseptic lotion or kept in a continuous bath for 48 hours. Experience on the railway has shown that such treatment surely makes a suppurating condition and those treated by thorough removal of all damaged tissue, arrest of hæmorrhage, proper cleansing with spirit, and a final pasting with B. I. P. P. followed by closing with sutures ensures in the majority of cases healing by first intention if done within 2 hours, and in other cases a lesser infection than has been obtainable by other methods. I would again lay stress on time after infliction before treatment is started as being of first importance in a country like India where the hot climate favours the commencement of septic processes with such dramatic haste. Below is an extract of reports received, for permission to publish which I am indebted to Dr. James Cairns, the Principal Medical and Health Officer, whose help and sympathy in arranging for the necessary equipment has made this endeavour possible.

At Jhansi.—Dr. Haworth reports 29 cases treated on an average 8 hours after infliction, healing on an average time of 14 days; and 2 cases treated on an average $\frac{1}{2}$ hour after infliction, healing on an average time of 6 days.

DURING 1923.

	Extent of wound.	Time elapsed before treatment.	Result.
At Wardha.	1" \times $\frac{1}{8}$ "	20 minutes.	Healed (not put on sick list).
	$\frac{3}{4}$ " \times $\frac{1}{4}$ " right foot.	2 hours.	Ditto.
	1 $\frac{1}{2}$ " \times $\frac{1}{4}$ " finger.	$\frac{1}{2}$ hour.	Healed in 7 days (put on sick list).
At Nagpur.	4" long.	1 $\frac{1}{2}$ hours.	Healed within 14 days (not put on sick list).
At Katni.	2" \times $\frac{1}{2}$ " irregular.	15 minutes.	Healed in 14 days.
At Jhansi.	1 $\frac{1}{2}$ " \times $\frac{1}{4}$ "	$\frac{1}{2}$ hour.	On sick list 9 days.
	1" \times $\frac{1}{2}$ "	$\frac{1}{2}$ hour.	On sick list 7 days.
	2" \times 1 $\frac{1}{2}$ "	$\frac{1}{2}$ hour.	On sick list 14 days.
	2" \times $\frac{1}{2}$ " \times $\frac{1}{2}$ "	$\frac{1}{2}$ hour.	On sick list 11 days.
	2" \times $\frac{1}{2}$ " \times $\frac{1}{4}$ " lacerated on inner part of foot while unloading stones.	About 10 minutes.	No discharge after 14 days. On sick list 23 days.

At Mannad.—The assistant surgeon reports 35 cases, of which 25 involved muscles, 4 had fractured bones and 6 had a large artery severed: 12 of these were treated within 2 hours and 23 later. The length of time in healing was approximately 11 days.

DURING 1924.

At Harda.—Four cases are reported. The wounds were from 1 inch to 3 inches long. All were treated within 2 $\frac{1}{2}$ hours and healed quickly; the largest kept its owner only 13 days on the sick list.

At Nagpur.—Seven cases are reported with wounds up to 2 $\frac{1}{2}$ inches long, they all healed quickly. The longest time on the sick list was 13 days.

At Bina.—The only case reported was unfortunate, being apparently a not extensive wound where no anæsthetic was used. It took 75 days to heal. The size was 3 inches by $\frac{1}{2}$ inch by $\frac{1}{2}$ inch and only muscles were involved. This case goes to show how difficult it is to thoroughly clean a wound without an anæsthetic.

At Byculla.—Five cases are reported, all of severe nature; in 2 there was fracture. The longest time on the sick list was 52 days and the shortest 21 days.

At Matunga.—Forty-five cases were so treated, a larger number than previously reported from any other station in charge of a subordinate medical man, due to the fact of the patients coming almost entirely from a workshop. Details of their severity are not given and the

length of time in healing is stated to be from 12 to 58 days. No anæsthetic was given in any of these cases.

At Kalyan.—Eleven cases are reported, most of which were extensive. They healed when under observation in from 4 to 21 days, a result which does much credit to the doctor concerned.

At Jhansi.—One hundred and thirty-six cases were reported, of which 95 per cent. are said to have healed by first intention. Fifty-five more cases involved deeper tissues including muscles, of which 90 per cent. are said to have healed similarly.

Eleven cases involving bones, tendons, large vessels and nerves, of which 80 per cent. are said to have similarly healed. The average time of being off duty at this station was 9 days for the first 136, 16 days for 55, and only 3 weeks for the 11 worst cases.

BOMBAY MILLPONDS AND ANOPHELINE CONTROL.

By Capt. B. S. CHALAM,

Officer in charge, Anti-malarial Operations, Back Bay Reclamation Scheme,

and

P. A. DALAL, L.M.S. (Bom.), D.T.M. & H. (Camb.),
Professor of Bacteriology, Grant Medical College,
Bombay.

A GLANCE at a large scale map of Bombay shows the northern half of the island to be studded over with a large number of millponds of shapes and sizes, which, however diminutive they may appear on the map, are on an average about three hundred feet by one hundred feet each. Owing to the introduction of electric drive in the Bombay mills, the majority of these ponds are no longer in use for the purpose for which they were originally meant, and form a potential source of breeding place for mosquitoes throughout the year. Luckily the species of anopheline mosquitoes found breeding in the city in the largest numbers—viz., *A. subpictus*—happens to be a non-carrier of malaria. Had it been otherwise, one shudders to think of the incalculable economic loss to a great industrial city from the ravages of malaria. As it is, the toll taken by this disease during recent years has compelled the attention of all concerned to the gravity of the malaria problem in Bombay.

Owing to the great extent of the breeding area and the profuse and various algæ growth that is seen in most collections of impounded water, control by oil or other larvicide is practically impossible. The debris and vegetation also afford protection to the larvæ against fish. Drainage or filling up of these ponds do not seem to be practicable propositions. Larvæ of *A. subpictus* and *A. stephensi* have been found thriving freely in these ponds many

a time, in addition to *Culex* and *Stegomyia* larvæ.

Remedy Suggested.—The usual methods of attack by oil, chemicals or other larvicide being impracticable, as also drainage or filling up of these ponds, we decided to adopt what was attempted very successfully in America in cases of impounded water under similar conditions. The site selected for experiment was a pond in one of the mills near Parel (Bombay) and was 270 feet long and 150 feet broad. The pond was covered with green algæ and anopheline larvæ were found with the greatest facility. An area of over 40,000 square feet had to be dealt with. On the 24th and 25th November, 1925, anopheline larvæ were found in this pond in large numbers at almost every dipping.

Use of Paris green.—On the 26th of November, 1925, we treated this pond with Paris green. Paris green is aceto-arsenite of copper. It was mixed with about 20 times its weight of fine cork dust. From what we have read of the use of it in the *Bulletins of the United States Public Health Service*, a dilution even of 1 in 100 of Paris green is said to be sufficient for larvicidal purposes. We have purposely used it fairly strong so that judging from the results of this experiment we could alter the strength in subsequent experiments. Dilution can also be made by mixing road-dust or fine sand and it is absolutely necessary that the diluent used should not be in the least degree moist, since moisture tends to cause the dust to sink. Kerosene may also be used as a vehicle for Paris green and sufficient kerosene is added to it to make a mixture thin enough to admit of being sprayed into the air. By virtue of the presence of oil, particles large or small float on reaching the water. Though a thin film of oil, even a continuous one is not sufficient to destroy larvæ, a quantity far less than that necessary to form a continuous film will suffice to float and aid in spreading the Paris green. However we prefer the dust dilution method and cork dust is an excellent diluent. Where the surface of water is free from scum a large amount of distribution takes place by air currents after the dust has reached the surface. But where the water is scum-covered a larger quantity of dust should be used. The Paris green mixture was distributed from the shore and also by means of an improvised raft in places which we could not reach from the shore.

Results.—On the 28th November 1925, two days after the treatment, we made several dippings for larvæ but could not find a single one, whereas larvæ occurred in easily measurable quantities before the treatment of the pond. On the 31st November 1925, again a very thorough search was made; 140 dippings were made and not a single larva could be found. This shows that destruction of

larvæ was practically complete. The experiment has been in part for the simple destruction of larvæ and also for the purpose of determining the time necessary for the repopulation by anopheline larvæ of areas in which larvæ have been completely destroyed. Sufficient time has not elapsed yet for determining the latter part of the experiment and this will be referred to in a subsequent note. It is also of interest to note that Paris green had no effect on aquatic insects like water-boatmen, water-bugs, etc., which were found in large numbers both before and after treatment of the pond with Paris green.

Cost.—We used 112 lbs. of cork dust and 5 lbs. of Paris green. One pound of cork dust costs about 6 annas and one lb. of Paris green costs about Re. 1-4. It took us about four hours to distribute the mixture and we employed four men for the work.

Risk of poisoning to Paris green mixers.—It is said that Paris green causes burns on the skin of parts of the body coming into prolonged contact with it and that it also causes irritation of the nasal mucous membrane. The burns are said to yield quickly to local treatment and the nasal irritation is said to disappear on discontinuing the work for a day or two. The precautions recommended are the use of simple masks over the nose and mouth during the mixing and spreading of the dust, and wearing a canvas or oilcloth apron to keep the dust out of the clothing. Also leather gloves should be used for the hands and the men should be encouraged to take a bath immediately after the operations. In the case of the labour we employed, there were no ill effects though none of the precautions mentioned above were taken. It would therefore seem that the precautions should be proportioned to the amount of contact with the dust, and in the case of persons using the Paris green only occasionally and for a short time as would be required in the control of a few ponds, it is questionable whether precautions are absolutely necessary.

Conclusion.—It would therefore appear that Paris green affords an ideal adjunct to anti-anopheline work. In the cases of large sheets of impounded water, as ponds and tanks and large swamps, where the use of oil or other larvicide would be enormously expensive and therefore impracticable, Paris green would appear to be a most valuable remedy to adopt. It is stated that domestic animals come to no harm by drinking the water of ponds treated with Paris green and that fish also are not killed by its use.

Public Health Bulletins of the United States Public Health Service.

ON THE INEFFICIENCY OF "MERCUROCHROME 220" IN THE TREATMENT OF MALARIA.

By J. D. DUNDAS, M.B., B.S.,
and

D. M. TELANG, M.B., B.S.,

Jamsetjee Jeejeebhoy Hospital, Bombay.

IN view of the reports on the favourable effects of "Mercurochrome 220" published in several recent papers, and especially with reference to the highly laudatory articles on the value of this drug in the *Therapeutic Gazette* in the issues of that journal for August and September, 1925, the following notes on six cases of malaria "treated" with this drug may be of interest. The patients were in the Senior Physician's wards at the J. J. Hospital, Bombay, during the month of November, 1925. The notes in the *Therapeutic Gazette* state that "the patients were discharged after a single dose, apparently cured, and with a negative blood examination."

All the cases were genuine ones of malaria, as determined by typical clinical signs and clinched by blood examination. As all of them gave almost identical results with regard to the drug, the particular type of malaria present is not of special significance. Suffice it to say that four of the cases shewed mixed benign and malignant tertian malaria infection, whilst the other two were instances of malignant tertian malaria only, every slide showing a fairly large number of parasites.

The urine before administration of the drug showed nothing particular.

In all cases a 1 per cent solution of Mercurochrome was given intravenously; the actual dose varying with the patient's weight, and being approximately 0.003 gms. per kilo. of body weight.

The samples of Mercurochrome used were:—(1) Messrs. W. Martindale's; and (2) Mercurochrome 220-soluble, of Messrs. Hynson, Westcott and Dunning, Baltimore, U. S. A.

The table appended shows the results with this toxic drug, and its inefficacy in the treatment of malaria.

In all these cases, except No. 2, quinine administration had finally to be invoked as the last resource, after which all five patients were discharged cured.

Conclusions.—(1) Mercurochrome 220 has no effect on malarial parasites, even after two doses, as in cases Nos. 1 and 3, as shown by blood examination after the reaction following upon its administration.

(2) Stomatitis and pyalism were marked features in every case.

(3) The drug appears to irritate the kidney tissue to the extent of producing mild nephritis, as was shown by examination of the urine in every case.

No. of Case.	Patient's weight. St. lbs.	Dose.	Reaction and rigor. Temperature nearly 102 F, coming down in 5 hours.	Blood (after reaction). Result of examination for parasites.	Urine after reaction.	REMARKS.
1	8 8	20 c. c. (1st day) 30 c. c. (2nd day).	Positive. Positive.	Positive. Positive.	Few R. B. Cs. and W. B. Cs. R. B. Cs. and W. B. Cs. increased.	Patient had pyalism next morning. Patient had marked stomatitis.
2	Could not be taken.	20 c. c.	Patient collapsed.	Positive.	Few R. B. Cs., W. B. Cs. and epithelial casts.	Patient was comatose from the very beginning. Collapsed heavily after the dose. Intravenous saline had no effect and he died. Autopsy showed:— (1) Splenic smears negative to malaria. (2) Acute parenchymatous nephritis.
3	7 6	15 c. c. (1st day). 20 c. c. (2nd day).	Positive. Positive.	Positive. Positive.	Few R. B. Cs. and W. B. Cs. R. B. Cs. and W. B. Cs. increased.	Pyalism followed the next day. Patient developed marked stomatitis.
4	4 6	15 c. c.	Positive.	Positive.	R. B. Cs., W. B. Cs., albumin and epithelial casts.	Marked stomatitis followed.
5	8 4	20 c. c.	Positive.	Positive.	Ditto.	Ditto.
6	8 7	23 c. c.	Positive.	Positive.	Ditto.	Ditto.

(4) It will be seen that this much-vaunted drug, which has been hailed as a veritable panacea—especially by some American physicians—in malaria, does not in any way affect the dominant position of quinine as a specific for malaria.

INDIAN DIGITALIS.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology;

and

PREMANKUR DE, B.Sc., M.B. (Cal.),

CAPTAIN, LATE I.M.S.,

Assistant Professor of Pharmacology, School of
of Tropical Medicine, Calcutta.

(Indigenous Drug Series No. 8.)

Introductory.

Digitalis purpurea, commonly known as fox-glove, is a biennial herb belonging to the natural order Scrophulariaceæ, or the figwort family. It was originally a native of western Europe but is now extensively grown in many parts of the world. There are a number of species of this plant having the same physiological action, though differing in the degree of their potency. For instance, *Digitalis*

purpurea is more effective than *D. compenulata* or *D. alba*, but *D. ambigua* from Austria shows a therapeutic activity equal to *D. purpurea*. For many years, preference was expressed for the English-grown leaf but during recent years Germany and Austria have supplied large quantities of good leaf to the world. During the war the supply from the German sources was cut off and the Americans tried to develop their resources. In California, Oregon and Washington digitalis grows wild and the leaves collected from these plants were found to be active and of sufficient potency to allow their use for medicinal purposes. One of the American-grown species is *D. lutea* which, therapeutically, is as good as *D. purpurea*, in fact it has the reputation of having less toxic effects on the gastro-intestinal tract.

In India a large amount of digitalis is used every year. This can be judged from the fact that Messrs. Smith, Stanistreet & Co., a firm of manufacturing chemists of Calcutta writing in 1912 said that they alone could use 3 to 4 cwts. of the Indian-grown leaf if it was as active as the imported leaf; the consumption has gone up considerably since then. Most of the digitalis used by the medical profession in this country is imported and the

problem has not only its economic aspect, but from the medicinal point of view the fact should be borne in mind that the digitalis preparations imported into India are liable to lose 20 to 40 per cent. of their potency in a very short time(1). We undertook the investigation of the digitalis grown in India in order to see if the Indian leaf and preparations made from it could be advantageously substituted for the imported commodity. Before entering into a discussion of the therapeutic efficacy of the digitalis leaf grown in different places in India it will not, we think, be out of place to give a brief account of the cultivation, methods of collecting, drying and storage, of digitalis leaf adopted in this country.

Cultivation of Digitalis purpurea in India.

So far as is known none of the species of digitalis are indigenous to India, but *D. purpurea* has long been grown in gardens in different hill stations as an ornamental border plant. As early as 1880 attempts were made to grow the plant in the Government gardens at Saharanpur and hill gardens in Mussoorie for a regular crop of leaves for medicinal purposes. The plant, however, did not flourish as it was reported to yield very few leaves and the cost of producing was higher than that of the imported leaf. Systematic cultivation was therefore for the time being abandoned in these places. In the Kumaon gardens the plant did better and in 1912 leaves were examined chemically by Martindale and found to be well above the standard so far as the active principles were concerned. The plant was cultivated in other places and the cinchona plantation authorities at Mungpoo near Darjeeling (Himalayas) and also in Burma took it up. It was also introduced into the Nilgiri Hills and now largely grows there from self-sown seeds, and the cinchona plantations supply it to the Government Medical Store Depôts at 3 annas per pound. As grown at Mungpoo it calls for very little attention in the matter of cultivation and grows well in open spaces at a height of 6,000 feet above sea level. Thousands of seedlings appear, so nurseries for rearing are not necessary. Before planting a new block, the ground is first cleared of jungle and dug to a depth of 1 ft. Then, with the aid of a rope, pegs are put in in rows 2 ft. apart and 10,800 plants are planted per acre. The plants are grown for about 12 months, during which time it may be necessary to sickle the block twice and to hoe it once during the cold season. When grown in this way the plant does well and yields a good crop of leaves.

Collection, drying and storage of the leaf.

Collection of the leaf.—Digitalis usually begins to flower in India about the end of April, and early in May, when the plants are in full bloom and two-thirds of the flowers on

each spike are fully developed, leaf picking commences and goes on throughout the hot weather. In Europe and America the leaves are also collected throughout the summer from July to September when the plant is flowering. The best product is, however, gathered in the early part of the summer, about the month of June, just before the flowers have expanded. It was recommended that leaves should be collected from plants of the second year growth, but investigations have shown that first year leaves have the same glucoside content as those of the second year, and in India leaves are generally gathered from plants, irrespective of their age. The leaves are plucked by hand, being twisted or broken off, without taking the thick fleshy leaf-stem. The lower basal leaves of poor colour are rejected, also the upper smaller leaves of the stem. Practically three-fourths of the total number of leaves per plant are taken, both young and old being mixed during collection. No particular attention is paid to weather conditions during the collecting period. It is at the beginning of the monsoon and the weather is usually dull and showery about that time.

Withering and Drying.—Each day's collection of leaves in this country is spread in thin layers on bamboo *machans* and left to wither for 36 hours, being turned over occasionally to prevent fermentation. Finally, drying is completed in a sirocco or even at a temperature of 150° F. Without the use of the oven it would be very difficult to dry the leaves thoroughly during the monsoon. Drying in an oven, however, has been shown to cause a marked deterioration, especially if the temperature is allowed to run high. Our experience with Indian leaf is that sun or air-dried leaves, such as those from Kashmir, retain their activity very much better than the oven-dried.

Storing.—After drying the leaves are stored in dark sheds. They are kept on the floor in a heap and covered with bamboo mats to exclude dust and light. Hatcher's recent work in America appears to show that no special precautions regarding storage, such as keeping the dried leaves in air-tight tins with perforated bottles containing freshly burnt lime, are necessary in that country. In warm and moist climates such as that of India, our experience is that unless such precautions are taken the leaf deteriorates in its therapeutic activity. Digitalis leaves kept in air-tight bottles in our laboratory kept their activity better than those left exposed to the moist air, especially during the hot weather.

Therapeutic activity of Indian Digitalis Leaf.

In 1913 Dr. Gordon Sharp carried out a biological assay of digitalis grown in India. He found that the Indian-grown leaf on casual

examination looked in every way like the ordinary wild or partially cultivated variety grown in England and Germany. Their taste was equally bitter. On closer examination the Indian leaves had a coarser stalk and the venation was somewhat coarser. The leaves themselves were darker and tougher than the European leaves but not much different from wholly cultivated leaves grown in the south of England. The tinctures prepared from these leaves were darker and contained more resinous matter than those prepared from the British or German varieties. Mungpoo leaf gave good results by biological assay by the "frog method" and by therapeutic trial on the human heart. Dr. Sharp pronounced that *D. purpurea* Linn. leaf grown in Mungoo was at least equal in potency to British or German-grown leaves. The leaf grown in the Nilgiris however failed to produce equally good effects.

yet when tested by perfusing an isolated mammalian heart it produced no increase in amplitude of the heart beat and no slowing as is usual with active tincture. Dr. Cow expressed the opinion that this negative effect on the mammalian heart need not condemn the sample and that it may possess adequate therapeutic properties which in this instance are overshadowed by the muscle poison effect.

In the end of 1922 the Government of India Medical Stores Department first sent the senior writer tinctures made both from Mungpoo and Darjeeling leaves and since then a number of other tinctures made from the leaf grown in India have been assayed. The assay was carried out by a modification of Hatcher's "cat method" (3). Chemical assay was also done at the same time by Kundson and Dresbach's chemical method. The following table shows the results that were obtained.

No.	Date of Assay.	Physical characters of dilute solution.	Percentage of slowing of intact mammalian heart.	H. T. U. per c.c. of tincture.	Amount in c.c. s. equalling 1 c.c. of standard tincture.	REMARKS.

<i>C. Tincture prepared from leaf grown on the Nilgiri Hills.</i>						
13	Early 1923	Dark blackish with ppt.	Nil	5.8	1.12	Very toxic when assayed by the "cat method."
14	Ditto	Ditto	Nil	5.2	1.24	
15	5-8-25	Ditto	Nil	18.0	0.36	
16	6-8-25	Ditto	Nil	13.2	0.49	
17	7-8-25	Ditto	Nil	17.1	0.38	

In 1920 Dr. Douglas Cow of the Pharmacological Laboratory at Cambridge assayed tinctures prepared by Messrs. Smith, Stanistreet & Co., from the leaves grown in Mungpoo and in the Nilgiris. One c.c. of tincture made from Mungpoo (Darjeeling) leaf was found to contain 8 H.T.U. (compared with equivalent standard of 1 c.c. = 6.5 H.T.U.). Its M.L.D. per gramme of frog was 0.125 c.c. Perfusion of the isolated rabbit's heart produced 100 per cent. increase in amplitude and 25 per cent. slowing. Dr. Cow pronounced the sample to be of adequate strength, showing reasonable therapeutic properties. In the case of the Nilgiri leaf he found that although by the "frog method" the tincture was found to be nearly double the strength of ordinary tincture—12.5 H.T.U. in a c.c. instead of 6.5—

DISCUSSION OF THE TABLE.

A perusal of the table will show that 17 specimens of digitalis leaf grown in India were assayed during the past three years. Eight of these specimens were from Mungpoo near Darjeeling, Eastern Himalayas; four from Kashmir, Western Himalayas; and five from the Nilgiri Hills in Southern India. It will be seen that the specimens from Mungpoo varied a great deal in their activity when tested by the "cat method." Some specimens (Nos. 1, 2, 6 and 7) were quite active, while the others (Nos. 3, 4, 5 and 8) were comparatively weaker. Slowing of the mammalian heart with these tinctures was also variable and was not so marked as in the case of Kashmir leaf preparations. These variations, in our opinion, were due to the method of drying and storing

adopted, which we have already described. It is difficult to maintain a perfectly uniform temperature in the ovens that are used, and if the temperature rises above 150° F. deterioration of the glucosides occurs, accounting for the loss of potency of the specimens. Storage of leaf also appears to have some bearing. Under the present conditions the leaf after drying is simply heaped up on the floor in darkened rooms and although the atmospheric temperature does not rise so high in the hills as it does in the plains, it becomes quite warm at times and as the air is full of humidity, fermentation is favoured and the glucosides are split up. These factors, in our opinion, are sufficient to account for the variations in the therapeutic efficiency of different specimens of leaf. Clinical trials with tinctures made from Mungpoo leaf showed that patients could be digitalised with reasonable quantities of this preparation (8 to 10 drachms per 100 lbs. body weight). We are of opinion that good quality of digitalis leaf can be grown in Mungpoo, and with improvements in methods of drying and storing adequate and reliable supplies could be obtained for therapeutic uses from this source.

The specimens of leaf from Kashmir gave excellent results both by biological assay and clinical trials. In Kashmir digitalis is not grown on a large scale and the specimens we examined were grown purely for experimental purposes. The leaves were dried in the sun and sent to us in air-tight tins. Kashmir is not affected very much by the monsoon, as in the Eastern Himalayas where Mungpoo is situated, and drying in the sun without the use of ovens is possible. The possibilities of growing digitalis in Kashmir would be worth considering. Freshly made tinctures from this leaf digitalised patients with 4 to 7 drachms per 100 lbs. body weight.

All specimens of leaf grown in the Nilgiris were very toxic and the lethal doses by the "cat method" were very small; there was hardly any slowing of the heart, which is an indication of its therapeutic activity. We are trying this tincture clinically in a series of cases in order to see if the negative effects on the mammalian heart mean that it does not possess adequate therapeutic efficacy.

SUMMARY AND CONCLUSIONS.

(1) Digitalis leaf of good quality grows in the valley of Kashmir (Northern Himalayas) and at Mungpoo (Eastern Himalayas).

(2) The leaf grown in the Nilgiri Hills is not so good when tested by methods of biological assay. Further clinical trials are recommended before the leaf can be finally condemned. The negative effect on the mammalian heart under experimental conditions may be overshadowed by the muscle

poison effect, and this may not occur when the drug is given by the mouth.

(3) Improvements in methods of drying and storage are recommended to get a uniform quality.

CONGENITAL YAWS.

By B. N. BANDYOPADHYAY, S.A.S.

Native Civil Hospital, Kakamega, Post Kisumu, Kenya Colony.

DURING the last six years I have come across many hundreds of cases of yaws amongst patients of all ages from a baby of 2 days old to persons of 75 or 80 years of age, in this district. Several babies brought into the Native Civil Hospital by their mothers in the first week of their life shewed peculiar yaws eruption on their bodies. Enquiries were made in each case in order to be sure whether they were suffering from congenital syphilis or not. I also tried my best to get some information from the parents as to whether they had suffered from syphilis previously or not. A thorough examination of the parent where possible was carried out, but did not disclose any evidence of syphilis, and in many cases the mothers gave the history of their having suffered from yaws. A few of them had been treated by me at this hospital as in-patients previously. Of course I believed those whom I could recognise and traced their names from the old records. At one time there were many children in the ward with their mothers suffering from yaws, and it happened that the Deputy D. M. S., Dr. C. J. Wilson, M.C., M.B., Ch.B., B.A., was at the station. I took this opportunity to settle my doubt, and showed him a few cases in the wards of this hospital in presence of the medical officer then in charge (the late Dr. B. W. Dakers), cases which I thought to be cases of congenital yaws. Dr. Wilson took particular interest and examined these cases. His reply was that there is no such thing as congenital yaws; on the other hand, he challenged me to bring to light a case with definite proof. Ever since I kept a watchful eye on every case of yaws and syphilis amongst babies. I consulted almost all the books that I could get on the subject, as also a text book of bacteriology, from which I quote as follows:—"Yaws is apparently not hereditary" (Byam and Archibald, *The Practice of Medicine in*

the Tropics). "Congenital yaws never exists, but a case is known suggestive of congenital transmission" (Dr. R. L. Spittal, Surgeon General Hospital, Colombo, Lecturer, Ceylon Medical College, in his book on *Framboesia Tropica*). "Yaws is neither hereditary nor congenital. A pregnant mother suffering from yaws does not give birth to a child suffering from the disease, nor one which will subsequently develop yaws unless the virus be first introduced directly through a breach of surface after birth" (Manson's *Tropical Medicine*, 1925).

Recently a baby was brought to me for treatment of yaws, two weeks old. The mother of this baby suffered from yaws about six months previously and was treated by me. Personally I am also acquainted with the father who suffered from syphilis about six years ago and had several courses of anti-syphilitic treatment with N. A. B., etc. He had two children born of his first wife, and they were both healthy. The third one is the baby referred to above, born of his second wife. I consider this baby to be suffering from yaws, probably of congenital transmission. The causal organisms are almost the same in both yaws and syphilis. Under the circumstances I fail to understand why yaws may not be of congenital origin, when syphilis often is of congenital origin.

Will other observers bring to light any other cases which may come to their notice, through the medium of your journal?

ANTIMONY AND FILARIASIS.

By P. RAJESWARA RAO, M.B., B.S.,
The Pochiraju Hospital, Berhampore.

It is regrettable that no remedy has yet been discovered to cure filariasis. This disease is very protean in its manifestations. Surgical aid, even where it is possible, does not seem to be an unmixed blessing. I have been trying antimony for the last four years in several cases and wish to note my experiences.

Antimony improves the lymphatic circulation in the regions affected with filaria. It may be that the filarial ova which are the chief cause of lymphatic obstruction are destroyed, and hence the improvement noticed after antimony injections. Filarial lymphatic glands subside very rapidly with antimony. I have also noticed that chronic ulcers over elephantoid limbs heal very rapidly with one or two injections. Chyluria and lymph scrotum show marked improvement. Lymphorrhagia stops miraculously with a few injections. Filarial orchitis improves a great deal with antimony.

Recently in a case of hydrocele I tapped the fluid and injected into the sac 3 grs. of sodium antimony tartrate in 10 c.c. of water. After

a slight swelling which lasted a fortnight the hydrocele was cured. The patient was not kept in bed and he was looking after his ordinary duties.

Method of injection.—Sodium antimony tartrate, scale preparation, is used and 1 to 1½ grains in 5 to 10 c.c. of distilled water is injected intravenously twice a week. Of late I have tried urea-stibamine and hope to get better results with a smaller number of injections. Joint pains are a marked symptom in many cases after 7 or 8 injections. Immediate cough and vomiting a little later on are quite common. With urea-stibamine I did not notice much cough or vomiting and as for joint pains, I have not yet tried a sufficient number of injections to decide on the matter.

In conclusion, I have not found till now any drug which is as efficacious as antimony to cure filariasis. The fact that several injections of antimony have not made the blood free from microfilariae may not militate against antimony treatment if it can cure the patients from the pathological effects of filariasis leaving microfilariae in the blood, as many persons harbour the filarial parasite with microfilariae in their system without any of its pathological manifestations.

THE TREATMENT OF CERTAIN CASES OF INTESTINAL OBSTRUCTION WITH BELLADONNA.

By B. D. PANDE, L.M.S.,
Offg. Civil Surgeon, Mainpuri.

BELLADONNA has a triple action on the intestines:—(1) It opens the gates, i.e., relaxes the sphincters; (2) it diminishes the spasmodic narrowing of the large intestines; and (3) it antagonises the vaso-constrictor action of the intestinal bacterial toxins and thus acts as a physiological antidote to them. The drug should be pushed to its full physiological effects, the result being most satisfactory if the treatment is started early.

A very large proportion of cases of intestinal obstruction yield readily to belladonna, but at the very outset have to be distinguished from the condition designated as "ileus." Whereas intestinal obstruction is a local condition causing stoppage of the intestinal current at a certain point, ileus on the other hand is a symptom-complex of toxæmia initiated by obstruction of the intestines chiefly by mechanical causes. The toxæmia is due to products absorbed from the upper intestine, especially the lower duodenum and upper jejunum.

To diagnose whether the obstruction is due to mechanical causes, an enema is administered of some irritating substance such as magnesium sulphate after washing the stomach in cases of toxic vomiting until the return is clear. In cases of mechanical obstruction

which sooner or later culminates in ileus, the gastro-intestinal tract being hypersensitive, this stimulus will cause prompt resumption of the vomiting and also cause pain in the region of the obstruction. If the obstruction is paralytic or simply toxic, the stimulus afforded by such an enema will provoke no result. The tract being hyposensitive, no pain will be caused nor will vomiting be resumed.

Reliance on other symptoms besides those

Whereas the former condition (intestinal obstruction) yields readily to intensive treatment with belladonna in massive doses, in the latter condition (ileus) nothing short of a prompt jejunostomy will ameliorate the symptoms.

Whenever the action of belladonna was found to be defective, physostigmine and pituitrin in combination have hastened the cure. One or two hypodermic injections at a few hours' interval suffice.

The following list well illustrates the effects of belladonna in cases of intestinal obstruction not advanced to the stage of ileus.

No.	Names.	Date of admission.	Date of discharge.	Results.	Approximate dose of belladonna, administered as tincture.	Symptoms.

2	Nand Kishore ..	7-3-25	9-3-25	Do.	„ ii	Do.
3	Budha ..	12-3-25	14-3-25	Do.	„ ii	Do.

of obstruction is put upon (1) pain, (2) tenderness, (3) rapid pulse, (4) severe shock, (5) vomiting, and (6) rigidity. These are all exaggerated in ileus.

Remarks.—All these cases were treated at the Sadar Hospital, Aligarh.

Treatment is started by administering xxx doses in a little water every hour till

physiological symptoms appear, when physostigmine and pituitrin are exhibited if the bowels do not start acting. In a certain proportion of cases where the bowels do not act of themselves, in order to start their action enemas of soap suds in lukewarm water should be given frequently, and also at intervals high rectal enemas to which a liberal amount of castor-oil or sweet-oil is added. This facilitates the easy passage of a hard faecal mass which may be acting as a plug. If the belladonna is not well tolerated owing to extreme sensitiveness of the stomach, hypodermic injections of atropine should be first started and then followed by belladonna by the mouth which is the route that is generally followed.

A Mirror of Hospital Practice.

A CASE OF SNAKE-BITE DUE TO *LACHESIS CANTORIS*.

By A. BAYLÉY-DE CASTRO,

Junior Medical Officer, Haddo, Port Blair.

MANY cases of snake-bite are annually treated in the hospital at Haddo, but as is usual the snake is never brought for identification and the majority of patients have failed to observe any particulars, or characteristics of the creature that has bitten them. An exception to this rule however occurred on the 30th July, 1925, when prisoner No. 32,315 came to hospital after being bitten by a *Lachesis cantoris*, identified as such.

He had been bitten between the third and fourth fingers of the right hand at 3 p.m. on the 29th July. At nine o'clock that night he had severe vomiting which according to his statement was of a bitter greenish-coloured fluid. He had spent a sleepless night due to excruciating pain in the arm.

On arrival at the hospital (11-15 a.m. 30-7-1925) the whole of the right arm was found to be very swollen, tense, and oedematous. Bullæ were found around the elbow joint, also posteriorly along the upper arm above, and the back and ulnar half of the forearm below. Temperature 98°, pulse 100, respiration 30; the patient was in great pain and was very restless. No abdominal pain was complained of nor was any tenderness elicited on palpation.

The pain extended up the arm from the fingers, then across the shoulder under the clavicle; also the course of the bullæ appeared to follow the line of the ulnar nerve, going up into the brachial plexus.

5 p.m.—Temperature 98°, pulse 98, respiration 20. There was a general reduction in the pain, and a slight abatement in the swelling around the shoulder. Patient was still restless. Suffered from constant eructation, the abdomen was slightly distended, and flatus was being passed. The bowels had not moved, but he had urinated twice. There had been no vomiting since admission. I am not certain whether the abdominal discomfort (eructation and flatulence) was due to involvement of the splanchnic nerves.

31st July, 1925.—Morning temperature 98°, pulse 88, respiration 20. Patient did not sleep till after midnight because of the pain. This morning he has none, but is still restless. The treatment adopted so far has been free incisions, and arm baths in a warm 5 per cent. potassium permanganate solution, one intravenous injection of calcium chloride (1 in 20), drinks of hot milk, and 2 oz. of rum b.d. A purgative of calomel grs. 6, followed by magnesium sulphate 6 drs. was also administered.

31-7-1925 (continued).—Evening temperature 98.4°, pulse 84, respiration 20. Bowels were moved thrice after the calomel, the stools being loose and yellow, there is no flatulence now. Restlessness has also gone. There has never been any epistaxis or subcutaneous hæmorrhages.

1-8-1925.—Morning temperature normal, pulse 86, respiration 20. The only swelling to-day is in the forearm and fingers, and that too is rapidly going. From to-day only antiseptic compresses are being used. The anxious expression has also left the patient.

Evening temperature 101°, pulse 92, respiration 22, benign tertian malarial parasites found in the blood.

2-8-1925. From this date onwards there is nothing further of interest to record about the case. No slough came away from the forearm and hand where the incisions had been made. The patient was finally discharged from hospital on the 20th August 1925.

The course of the pain from the fingers upwards seemed to have travelled along the course of the ulnar nerve and then the brachial plexus. I think it possible that the abdominal discomfort, flatulence, distension and eructation may have been due to involvement of the splanchnic nerves, but why so long after the bite I cannot understand.

From the notes on the case it will be seen that the respiration and pulse were both slightly accelerated. How much fright accounted for this cannot be said. That there should have been no sloughing is also a point to note. One other common snake in these Islands is the *Lachesis purpureomaculatus* (Gray's pit viper), and I am hoping before long to have the opportunity of recording the effects of the poison of this viper also.

Postscript.—Since writing this article I have been in correspondence with Colonel F. Wall, I.M.S., who is of the opinion that the three snakes *L. gramineus*, *L. purpureomaculatus*, and *L. cantor* can hardly be considered distinct species, and that the two latter are merely insular forms. A careful analysis of the lepidosis of the three shows only differences in the scale rows.

A CASE OF PERSISTENT HICCOUGH TREATED SUCCESSFULLY BY INJECTIONS OF NOVOCAINE INTO THE PHRENIC NERVE.

By D. M. GHOSE,

Assistant Surgeon, Sitamarhi, Muzaffarpore.

Hiccough is caused by clonic contractions of one or both sides of the diaphragm, and therefore the diaphragm should be examined with x-rays before undertaking any surgical measures for the relief of this disorder. A case of intractable hiccough came under my treatment some time ago. Jasodia, a local Brahmin girl, was seen in consultation with a local practitioner. Her condition was very bad, as she could not retain any food or even water in the stomach for the previous two months, the duration of the hiccough being nearly $3\frac{1}{2}$ or 4 months. It is amazing how she could keep up her nutrition for such a length of time without practically any food. She was also treated at two other headquarters stations for some time without any appreciable benefit. Her father as a last resort brought her back to this place. She was at that time reduced to a state of profound exhaustion and she had at times great pain in the region of the diaphragm. The urine and stools were practically stopped for more than a week. Ice was tried and even that could not be retained. The hiccough used to stop during the short snatches of sleep she had at night. She had no fever, the face was rather pale and slightly œdematous with a trace of albumin in the urine. There was nothing abnormal in the heart or lungs. The nervous system was slightly defective as she could not speak properly, and some of the reflexes (especially the knee-jerks) were slightly exaggerated.

When all remedies like morphine, chloral, gelsemium, cocaine, etc. failed, acting on the suggestion of Kroh, I infiltrated the phrenic nerve with novocaine injections ($\frac{1}{2}$ —1 per cent. solution, 2 to 4 c.c. dosage) on one side of the neck. This brought on a transient pain in the shoulder of the same side and the chest. Next day 3 c.c. was injected on the other side. With the third injection there was found some improvement in that she could retain ice, and the number of contractions was less frequent. Encouraged by this result I repeated the injections daily till altogether six were given,

when the hiccough completely subsided. She could then retain liquid food. Of course she was being fed up with nutrient enemata for some days before the injections were started but these had to be abandoned as her parents and relatives did not like them. The patient has had no relapses of this disorder now for eight months after this stoppage.

The following is the technique of Kroh, which I followed in the above case:—

The needle is inserted about 2 finger-breadths above the clavicle, close to the outer border of the sterno-mastoid muscle. The anæsthetic is injected as the needle is thrust vertically towards the scalenus anticus muscle on which the phrenic nerve lies, the depth to which the needle is passed being 2 to 4 cms. according to the amount of fat in the neck. When the phrenic nerve is reached the patient complains promptly, as a rule, of transitory pain in the shoulder and region of the heart; sometimes also in the upper abdomen. It is not incumbent on the operator to make sure that the injection is strictly intraneural, for an infiltration anæsthesia of the structures about the nerve is adequate. Kroh further advocates unilateral or bilateral partial phrenicotomy if the above simple procedure fails. Kroh does not give the dosage and the strength of the solution of novocaine but I adopted $\frac{1}{2}$ to 1 per cent. solution and made the first dose 2 c.c. and increased to 4 c.c. gradually.

TWO INTERESTING CASES OF LIVER ABSCESS.

By MATLOOB KHAN, I.M.D.,

Jemadar, Barsar Dispensary, Kangra District.

IN view of the report in the *Indian Medical Gazette* for October 1924, p. 488, by Captain A. Sargood Fry, I.M.S., of spontaneous absorption of large abscesses of the liver under emetine therapy alone, without even aspiration, the following two cases may be of interest. In the first a large abscess was present, and, with the exception of 1 c.c. of pus withdrawn by a hypodermic syringe in order to confirm the diagnosis, cleared up spontaneously on emetine therapy alone, without aspiration; in the second, invasion of the lung had occurred, but yielded completely to emetine therapy.

Case 1.—Gobind, aged 46, Hindu male, a cultivator, was admitted to hospital on 5th January 1925. On admission he was bed-ridden, very much emaciated, sallow and anæmic. There was no history of previous dysentery or diarrhoea, but the bowels were habitually irregular, even constipated.

In the right hypochondriac region was a prominent bulging swelling, extending downwards to within one finger-breadth of the umbilicus, occupying a large part of the left hypochondrium also, extending in the right axillary line to $5\frac{1}{2}$ finger-breadths below the

costal margin, and above to the 5th rib. At the back the dullness reached to $1\frac{1}{2}$ inches above the inferior angle of the right scapula. The abscess was pointing near the junction of the 9th costal cartilage. There was deficient expansion of the right lung and bulging of the right side of the chest. The evening temperature was 101° F., and oedema was present on the legs. Thus there was no doubt that a very large abscess of the liver was present. The area was also very tender on pressure. The duration of symptoms had been three months: they had become very acute during the previous 20 days.

The patient was immediately put on to emetine hydrochloride gr. 1 hypodermically daily, whilst a mixture containing ammonium chloride, potassium iodide and belladonna was given orally. Relief was immediate and amazing. After the 3rd injection and third day of treatment the temperature became steadily normal the patient slept well, pain disappeared, and his appetite was good. He refused, however, to submit to the experiment of trying treatment with emetine alone, without any measures being taken to evacuate the pus, and even made the accusation that the diagnosis was wrong. Accordingly liver puncture was performed with a hypodermic syringe only on the 5th day after admission in the 7th costal interspace in the right mid-axillary line, and the pus was shown to the patient. Only 1 c.c. of pus was withdrawn, and that solely in order to satisfy the patient's demands.

On the sixth day there was evidence of pleural irritation, and probably some pus had escaped into the pleural cavity. The patient complained of renewed pain and was very restless. Morphia and atropine were given hypodermically. Despite his protests, however, I refused to aspirate the pus, believing that the condition would clear under emetine therapy alone. By the ninth day after admission, all pain had gone, and the patient was comfortable.

The subsequent course of the case was uneventful. A second course of 12 daily injections, each of 1 grain of emetine hydrochloride, was given between the 19th February and 2nd of March. In all he received 24 injections, each of 1 grain of emetine hydrochloride subcutaneously. The abscess became slowly absorbed, and the swelling gradually disappeared. He was up and walking about with a stick on the 25th January, (20th day after admission). Expansion of the right lung improved only gradually. He was discharged from hospital on the 2nd March. At that time the liver dullness extended only half a finger-breadth below the costal margin and the left hypochondriac swelling had completely disappeared. He was seen again as an out-patient on the 13th of March and 31st March. By the latter date he was working in

the fields, there was no evidence of any enlargement of the liver, the border of which had sunk below the costal margin; the expansion of the right lung was satisfactory, and he appeared to be in sound health.

The case is a very interesting one from several points of view. Only 1 c.c. of pus was withdrawn, and that merely to satisfy the patient as to the diagnosis. The first course of 12 emetine injections probably killed the entamoebæ and subsequently the sterile abscess slowly resolved of itself during the next month and a half. A marked feature of the case was the patient's improvement in weight, despite the absorption of this very large abscess: on January 23rd his weight was $42\frac{1}{2}$ seers; on February 8th it was $44\frac{1}{2}$ seers.

Case 2.—Bishan Dai, Hindu female, aged 14 years, was first seen as an out-patient in December, 1924. There was no history of previous dysentery or diarrhoea, and no family history of importance. She then complained of fever and of a painful swelling in the right hypochondrium. A diagnosis of liver abscess was made, and emetine injections advised. To this her parents refused to consent.

In March 1925, she was shown to Capt. H. Chand, I.M.S., Civil Surgeon, Kangra, who also made the same diagnosis and advised emetine therapy. The parents again refused to allow this.

On the 2nd September 1925 I saw her at her home, as the parents refused to bring her to hospital. I found her in a state of acute agony and with high fever, a temperature of 104° F. She was profoundly anæmic and slightly jaundiced. The tongue was coated and furred, the appetite was almost nil, and she had had very little sleep. Occasional attacks of hæmoptysis and coughing up of pus were present. Respiration was hurried and 36 per minute. The right side of the chest was partly immobilised, on percussion dull all over the lower lobe, vocal resonance ++, vocal fremitus ++++. A diagnosis was made of hepatic abscess bursting into the right lung with secondary pneumonia. The parents were urged to send the child into hospital, but again refused. She was accordingly treated as an out-patient, being brought to the hospital daily in a dooly.

Treatment was commenced by a daily purgative and emetine hydrochloride, gr. 1 hypodermically daily for 12 days. A stimulant expectorant mixture was given by the mouth.

For the first two days, relief was but slight, but the third and fourth days showed tremendous improvement in the patient's condition. The temperature came steadily down by lysis, and reached normal on the 10th day, subsequently to which it did not rise again. Hæmoptysis and expectoration steadily diminished and pain disappeared; sleep was normal and the appetite became good. For a month after

the temperature became normal she was given a mixture containing potassium iodide, belladonna and expectorants, with ammonium chloride. The symptoms gradually subsided and the chest cleared.

A second course of emetine injections was advised at a later date, but the patient did not attend for it. She was last seen on the 16th December 1925. There was no fever and her general physical condition was good, whilst she was working at her daily duties. The right lung was completely clear. The liver, however, was still enlarged to $3\frac{1}{2}$ finger-breadths below the costal margin with slight tenderness on deep pressure.

I am indebted to Captain H. Chand, M.C., I.M.S., Civil Surgeon, Kangra, for permission to publish the notes on the first case.

A CASE OF CERVICAL RIB CAUSING UNILATERAL BRACHIAL NEURITIS: OPERATION WITH AMELIORATION OF SYMPTOMS.

By J. N. SEN, M.B. (Cal.), M.R.C.S. (Eng.), L.R.C.P. (Lond.),

Deputy Chief Medical Officer, Tata Iron and Steel Co., Jamshedpur.

A BENGALI gentleman, one of Tata's employees, came to my consulting room in July

hand were wasted and she complained of pain along the whole length of the right arm. In the course of my examination I came upon a hard elongated mass on the right side at the root of the neck, pressure over which caused pain along the arm and obliteration of the radial pulse. Not having any x-ray apparatus in the equipment of our hospital I asked the husband of the patient if he could take her to Calcutta for an x-ray photograph to confirm my suspicion of the presence of a supernumerary seventh cervical rib.

Owing to the straitened circumstances of the man he agreed to my proposal rather reluctantly and he brought me a plate after a fortnight or three weeks. The photograph is herewith appended, which shows the presence of a complete cervical rib on the right side and an incomplete one on the left side; the distal portion of which does not show in the photograph, probably owing to its fibrous condition, which also accounts for the absence of any symptoms on the same side. The following is the history of the patient after she was admitted to hospital.

Mrs. C., aged 20 years, married, admitted for the treatment of pain in the right upper extremity extending from the right shoulder-blade up to the fingers of the right hand, more along the inner side of the limb. She

last and asked me if I could give him some good liniment for pain in his wife's arm from which she had been suffering for a long time. On questioning him in detail he told me that in addition to the pain the right hand looked much thinner than the left. Thinking it to be a case of some nervous disease I told the man that I would come and see his wife. A week or so after I saw the patient in her house and found that the intrinsic muscles of the right

describes this pain as being of a gnawing character and says that she has been suffering from it for the last 5 or 6 years without any impairment of muscular strength or tactile sensation. The pain is relieved by pressure over the affected limb. For the last year and a half this pain has increased in intensity. At times the pain is very slight, especially after perfect rest of the limb, and at other times it gets worse, especially when she hangs the

limb for a long time or after manual work. For the last year and a half she has noticed that the right hand is getting thinner with slight loss of muscular strength. She has also been feeling a tingling and numbness along the arm for the last year and a half.

Present condition.—She is a well-nourished young woman of 20, mother of one child. There is nothing particular to note about her family or personal history. The thoracic and abdominal organs are normal.

Nervous system.—There is no alteration in tactile or painful sensation in the affected limb, neither is there any change in the temperature sensation. The thenar and hypothenar muscles of the right hand are atrophied, especially the hypothenar muscles. The interossei muscles are also atrophied. The muscles above the wrist are unaffected. The pupils are equal on both sides. There is no abnormality in any of the superficial or deep reflexes.

DIFFERENTIAL DIAGNOSIS.

(1) Brachial neuralgia. The atrophy of the small intrinsic muscles of the hand at once removes the case from the category of brachial neuralgia.

(2) Progressive muscular atrophy. The absence of paralysis of other groups of muscles in the forearm and upper arm in spite of the long duration of the disease differentiates it from progressive muscular atrophy.

(3) Syringomyelia. The absence of dissociative anæsthesia and of trophic and vasomotor disturbance excludes it from syringomyelia affecting the 8th cervical and first dorsal segments of the cord.

(4) Acute poliomyelitis can be excluded by the absence of fever, headache, vomiting, and convulsions.

(5) Peripheral neuritis is generally bilateral and sensory symptoms are more marked.

(6) We have then only to consider the big class of brachial neuritis. Let us take one by one the causes of brachial neuritis:—(a) Tumour in the posterior triangle of the neck; (b) glands in the axilla; (c) aneurysm of the subclavian artery; (d) malignant disease or caries or gumma of the cervical vertebrae; (e) cervical pachymeningitis; (f) spinal tumour or spinal gliosis; and (g) cervical rib.

(a), (b), (c) and (d). There was no evidence of tumour nor could any enlargement of the axillary glands be discovered nor any sign of aneurysm of the subclavian artery to account for the symptoms; caries and malignant disease of the spine are excluded by the absence of any deformity or pain over the cervical spine. (e) Cervical pachymeningitis is generally bilateral. (f) Spinal tumour and spinal gliosis can be excluded by the absence of any cord symptoms. (g) Cervical rib was presumably the cause of the neuritis, as an elongated mass could be felt at the root of the neck,

which presumption was corroborated by the x-ray photograph.

Operation.—On August 22nd, a vertical incision was made over the brachial plexus in the posterior triangle of the neck on the right side. The incision was deepened until the levator anguli scapulæ and scalenus medius were defined. The external jugular vein was held aside. The brachial plexus was defined and the middle portion of the cervical rib exposed. Owing to the difficulty of space in the operation area a transverse incision was made along the superior border of the clavicle, commencing from the lower angle of the former incision right up to the sternocleidomastoid muscle. The flap of skin was turned to the inner side. The external jugular vein had to be ligated and cut as it was coming in the way. The posterior belly of the omohyoid was hooked down. The subclavian artery was pressed down by the assistant. The brachial plexus was pulled aside and about an inch of rib, which was lying against the brachial plexus was defined. Not daring to go any further up and down the rib for fear of wounding the dome of the pleura and to avoid severe traction on the brachial plexus that portion of the exposed rib was excised with a rongeur and bone-forceps. This freed the brachial plexus from immediate pressure of the rib. The wound was closed in the usual way. She made an uneventful recovery except for a rise of temperature on the 4th day up to 102°F. which was due to malaria as proved by the examination of her blood. Full doses of quinine checked the fever and she was discharged on 31st August, 1925.

Remarks.—The immediate result of the operation on the second day was disappearance of all pains. She was free from pain till she left the hospital. At the time of writing I hear that slight pain has returned over the upper arm. If the pain increases I intend to tackle the proximal portion of the rib from behind if the patient agrees to the operation.

Since writing the above I saw the patient about a month ago and she is now quite free from pain and does all her household duties.

My thanks are due to my assistant Dr. P. N. Sen Gupta for compiling these notes for me and to Rai Bahadur Dr. S. Chakravarti, the Chief Medical Officer, for his suggestions and help in the operation.

A CASE OF VESICAL CALCULUS WITH ENLARGED PROSTATE IN AN OLD MAN.

By KHUSI RAM,

Assistant Surgeon, Shorket Hospital, Jhang District.

An old dhobi named Mohammed, son of Ali, 85 years of age was brought to this hospital

with retention of urine, and in a state of considerable emaciation. On examination a small calculus was found impacted in the urethra near the urethral orifice. This was removed with some difficulty and only after enlarging the orifice, and the patient could then micturate, but I suspected another stone in the bladder. On sounding the bladder a hard stone was found, together with considerable enlargement of the prostate.

The patient was fully prepared for either suprapubic or perineal lithotomy, anaesthetized and placed on the table. I first tried litholapaxy, but even the largest sized lithotrite failed to break the stone as it was both large and hard. I then decided on the perineal operation—in preference to the suprapubic one—as one or two previous cases of suprapubic prostatectomy had died from hæmorrhage and exhaustion, whereas none of my cases of perineal prostatectomy had died.

On perineal incision and exploring the bladder, the enlarged prostate obstructed delivery of the stone. Accordingly the prostate was first enucleated and the stone then extracted. It weighed 4 ozs. Fortunately there was but little hæmorrhage; the bladder was washed out with boric lotion, a drainage tube put in, and the wound packed with gauze. Twenty minims of tinct. opii were given hypodermically the patient kept warm, and given a fluid diet and urotropin, grain 10 t.d.s.

The wound healed slowly, and required touching with caustic lotion for two or three days, but the patient made a complete recovery, and was discharged cured about a month after operation. The recovery of so old a patient in a *mofussil* dispensary with no adequate nursing arrangements, and only two dispensers to help me, was remarkable. He shewed no shock, developed no bed-sores, and escaped hypostatic congestion of the lungs.

A CASE OF COMPLETE AVULSION OF THE SCALP.

By W. L. BROOKES,

MAJOR, I.M.D.,

Civil Surgeon, Northern Shan States, Lashio.

I SEND herewith a photograph of a case of complete avulsion of the scalp which may prove interesting to your readers.

The man concerned was an old Burman of about 60 years of age. He was attending to his sugar-cane mill—the usual type of crude mill worked by bulls yoked to a shaft pivoted on to a heavy wooden mill which is revolved by the bulls moving in a circle round the mill. The old man was bending over the crushing blocks to remove sugar-cane debris when his long hair got undone and was caught in the mill. The bulls continued to move round in a circle which resulted in his hair being wound into the mill. He was dragged round the mill

and fruitlessly tugged to get free. His shouts accelerated the pace of the bulls. At length the scalp gave way and the old man collapsed on the ground. He was found there by others shortly afterwards and brought to hospital in a cart the following day. He was in a low condition suffering from shock and hæmorrhage with high fever, but except for a little oozing here and there, active bleeding had stopped. The raw skull surface was covered with chaff, sugar-cane debris and rubbish from the ground in addition to dried blood clots. It was with difficulty cleansed with hot saline lotion and several bleeding points had to be arrested. Before final dressing several skin grafts were applied, taken from the inner surfaces of the thighs and upper arms of the old man's sons, who were willing donors. Further grafts were applied on two successive days. Injections of anti-tetanic and anti-streptococcus serum were given and the patient was kept more or less under the influence of morphia for a week, during which period he was in pain and had a high temperature.

Except for the areas bared almost to the bone, several of the grafts took. The patient was convalescing satisfactorily but healing was slow, so his relatives removed him to his village before final recovery.

AN INTERESTING CASE OF NARCOTIC POISONING AND RECOVERY.

By R. SUNDARA RAJAN, M.B., B.S.,

Raja Street, Coimbatore.

ON August 27th, 1925, a man named Rama Naickan, aged 49, belonging to the agricultural class, took a quantity of the roots of the blue variety of *Clitoria ternatea*—(Tamil—*kakkanangodi*; Malayalam—*sangupushpam*; Hindi and Bengali—*aparajita*; Kanarese—*vish-*

mugranti) ground well, and mixed into an emulsion with coconut milk. He took this on the advice of a local *vaidyan* as a purgative. He was also advised to take some curd and rice after he had two or three motions. This the patient neglected to do. He had during the day 5 or 6 motions and about a similar number of attacks of vomiting. The patient gradually lost strength and consciousness, till at 6 p.m. he became completely prostrated and unconscious. His body had become quite cold and he became deaf to all calls. I was called to see the patient at 8-30 p.m. and I found him in a state somewhat similar to that of one in a condition of cerebral irritation. He was extremely irritable, was lying on one side, breathing stertorously, his eyes half closed, saliva running down his cheeks and he now and then spat on the ground about him. His legs were stretched out and were kept rigid. His pulse was feeble and slow, about 50 per minute. His heart sounds were not well heard. When I saw him he was already warmed externally with hot ash, but his temperature at the axilla was 96°F. I gave him stimulant injections and a hot coffee enema. I also ordered an enema of thin broth in the course of the night.

During the whole of the next day the patient was still unconscious, and I repeated the injections and enemata. A peculiar feature in his case was that in whatever state of unconsciousness, he would get up from his bed and walk a few steps to pass urine. He passed urine rather frequently every two hours. Attempts at feeding by the mouth were unsuccessful until the evening of the next day when he took a few spoonfuls of milk. He passed no motions after I was called to see him. At about 8 p.m. next day, I gave him an injection of digitalin as I thought the heart was still rather weak, and at about midnight he recovered and began to talk, after nearly thirty hours of unconsciousness.

I wish to bring this case to notice on account of two salient features viz.—(1) the unconsciousness attended with extreme irritability, with retention of visceral reflexes such as that of micturition; and (2) during the stage of convalescence, for a period of more than a fortnight, the patient exhibited a peculiar loss of memory for some recent events which happened prior to his attack. Also he was unable to say how he took the drug or how many motions he had had and so on. Gradually he got over his mental condition and was all right in a month's time.

The root of *Clitoria ternatea* is very commonly given by *vaidyans* in India as a powerful cathartic. Watts' *Dictionary of Economic Products* gives us a detailed account of the drug and its various medicinal properties. The root is a powerful diuretic, as is also exemplified in this case. There are two chief

varieties of the plant, the white-flowered and blue-flowered, the former being the commonly used plant. The patient, as mentioned at the outset, took the roots of the latter variety. It would be interesting to know whether any cases of poisoning by this drug have been recorded and whether the symptoms in my report are in any way peculiar.

A CASE OF FIBRO-CYSTIC TUMOUR OF THE UTERUS. HYSTERECTOMY.

By ERNEST F. NEVE, M.D., C.M., F.R.C.S.E.,

Senior Surgeon, Kashmir Mission Hospital.

ZERA, act, 26, was admitted on October 26th 1925, with a history of abdominal swelling for some months; married, nulliparous. The history of menstruation was regular, but with painful periods associated with constipation. On physical examination an oval swelling was evident, the size of a large coconut, centrally situated, projecting half-way to the umbilicus and fluctuating on palpation. The cervix uteri was long and pointed. The uterus could not be differentiated from the tumour. There were no enlarged glands palpable. The diagnosis lay between a cystic ovarian tumour and uterine fibroid.

On November 2nd, on operating, I found a large cystic tumour exactly like an ovarian cyst. On passing a large trocar and cannula, about two pints of chocolate-coloured fluid were evacuated, closely resembling the contents of an ordinary ovarian cyst. I found, however, that the tumour had developed from the posterior wall of the uterus, so did a supra-cervical hysterectomy, saving both ovaries. The patient made an uneventful recovery and was discharged cured on November 17th.

The tumour was surrounded by a definite and vascular capsule. The fluid contained Foulé's cells. The walls of the cyst, which was monolocular, shewed patches of yellow, partly organised, lymph. On section, the substance of the walls was chiefly fibrous tissue with islands of uterine muscle. It seems probable that, originally a fibroid tumour, the centre of the mass had degenerated and had formed a cavity in which fluid accumulated, and the mass expanded under pressure, forming a fibro-cystic tumour. The cells in the fluid contents were rather suggestive of malignancy, but the walls of the tumour itself did not present any characteristic malignant structure.

Remarks.—One of the chief points of interest in this case is the question of diagnosis. In this patient, pregnancy could be excluded. But it was not so easy to be certain that it was not an ovarian cyst. Everything pointed to its being an ovarian cyst except the fact that the uterus could not be differentiated

from the tumour. Even so, the cystic character was puzzling, owing to the rarity of this type of degeneration.

A CASE OF NIGHT-BLINDNESS DUE TO *ASCARIS LUMBRICOIDES* INFECTION.

By A. R. HARIGOPAL, L.C.P. & S.,

Assistant Medical Officer, Civil Hospital, Nampalli, Hyderabad, Deccan.

HAFIZ, son of Shaikh Imam, a young Mahomedan boy aged 6 years, was brought to the out-patient department with a history of night-blindness of some duration. He had had a similar attack six months previously. Blindness used to come on directly after sunset each evening, whilst if he left a brightly lighted room for a darker passage, he had to grope his way.

There was no history of any serious illness, and no evidence of hereditary syphilis. He looked healthy, but had a very protuberant abdomen. On ophthalmoscopic examination both eyes appeared to be normal. The urine showed no albumin. The spleen and liver were not enlarged.

There was a history, however, of his having passed worms, and of grinding of the teeth during sleep and of convulsions at the age of 2 years. Accordingly santonin and calomel were given, followed by castor oil. A large number of round-worms were passed, after which the night-blindness cleared up completely.

During the past two years I have seen other similar cases where treatment for *Ascaris* infection has cured a condition of night-blindness.

A CASE OF EMBOLISM OF THE SPINAL CORD.

By M. P. CHACKO, L.M.S.,

Assistant Surgeon, Medical Officer, Lalom, Pala P. O., Travancore.

In infective endocarditis embolism of various arteries and infarcts are common, but embolism of the vessels of the spinal cord appears to be a rare phenomenon. Further, embolism of the vessels of the spinal cord due to an embolus from an infected wound appears to be exceedingly rare. Hence the following case is of interest.

Thommen, aged 35 years, ryot, was admitted to the Lalom Hospital on 15-8-1925, with a history of complete paralysis of the lower limbs of 15 days' duration. He had extensive varicose veins of the left leg for which he was advised by a quack doctor to apply leeches. He applied three leeches to the varicose veins, but the blood oozed from the wound for three days together. He applied certain remedies to stop the bleeding, with success. That night at 10 p.m. he went out as usual to pass urine. On rising he felt a loss of power in the limbs

as if something had given way beneath him and he dragged himself with difficulty to his bed. Hot applications were made to his extremities without success. Since then he is bed-ridden and has incontinence.

On admission he had complete loss of sensation and motor power in the lower extremities and anaesthesia below the level of the umbilicus. He had incontinence of urine and faeces and cystitis. He also had burns of the third degree on the dorsum of the feet, which occurred as the result of local application of heat by his too zealous relations.

On examination his heart was normal. He had no history of rheumatism or syphilis. On the dorsum of both feet there was a large burn of the third degree, quite painless and sloughing. There was absolute loss of power and sensation from the costal margin downwards. There were no zones of hyperaesthesia. Neither superficial nor deep reflexes could be elicited in the lower limbs. The bladder was distended. The urine drawn off by catheter was ammoniacal and contained albumin and pus. There was incontinence of urine and faeces. The pulse was 84, regular and of normal tension. The spleen and liver were not palpable.

Despite irregular pyrexia, his general condition slightly improved but the paralysis was unchanged. As he wanted to return home, he was discharged on 23-8-1925.

It may be reasonably inferred that the patient had one or more emboli lodged in the spinal vessels. Charters Symonds (1) states that it is in cases of mild phlebitis that the detached blood clot is formed. The emboli coming from the inflamed varicose vein rapidly produced softening over an area greater than that supplied by the plugged vessel. This explains the ingravescent nature and the completeness of the paraplegia. The infected embolus sets up an acute myelitis. Softening of a definite portion of white or grey matter may also in certain cases be caused by depriving it of its blood supply by the injection of artificial emboli and the resulting degeneration may be studied. For instance, fine particles like lycopodium spores are injected into the abdominal aorta between the origins of the renal and inferior mesenteric arteries. They are prevented by clamps from entering those vessels and passing through the lumbar arteries stick to the branches of the anterior spinal artery and cause softening, mainly of the grey matter of the lumbar portion of the cord.

Corrigendum.

In connection with Assistant Surgeon Romendra K. Basu's account on p. 24 of our issue for January 1926, of a case of very severe abdominal injury successfully treated by operation, in the second last line of the page for "was discharged cured," please read "was discharged cured after two months in hospital."—EDITOR, I.M.G.

MARCH.

SOME IMPRESSIONS OF JAPAN.

THERE is a fatal tendency for globe trotters to form opinions on insufficient data and as my impressions of Japan were formed during a brief stay of about three weeks, their value is limited by the circumstances under which they were formed.

For many years Japan has appealed to the imagination of the people of the West, not only to those who belong to the literary and artistic sections but also to the masses.

Japan is regarded as a land of romance and if the Japanese complain of being misunderstood, it is because they have been idealised and have been regarded as heroes and artists rather than as men of affairs. The Japanese themselves are under no illusions, they know only too well that their country has its hard problems of every-day life and they are setting about the solution of these problems in an earnest and business-like manner. They rather resent the atmosphere of unreality which has been introduced into descriptions of themselves and their country, and though they feel that they cannot convey to the foreigner true and unbiassed opinions about Japan, yet they are acutely conscious of the false impressions that exist.

To the medical man Japan offers materials for study which are of great interest; the introduction of scientific medicine into Japan took place in much the same way as the introduction of modern methods of business, warfare and science. In ancient times much of the indigenous medicine of Japan was of Chinese origin and tradition held an undisputed sway. The teaching of anatomy was based, not on dissection of the human body, but on books and pictures whose accuracy was accepted without question.

When the western books of anatomy found their way into Japan it was at once noticed that the descriptions of the human frame which were contained in them did not agree with those which were found in the Japanese books. The first explanation which was offered by the followers of the indigenous system was that the structure of the foreign barbarian would naturally be quite different from that of the Japanese, who are descendants of the gods. This view was not accepted by the younger generation which had already learned

the great lesson of science "do not argue or theorize, but examine for yourselves." When the great step of dissecting the human body was taken, it was found that the bodies of the Japanese were exactly similar to those of Europeans as described by western anatomists. With characteristic honesty the Japanese at once became converted to the methods of observation and experiment, and though quackery still prevails in Japan, as it does in every other country, all educated Japan is solid for scientific medicine. Germany may be described as the spiritual home of Japanese modern medicine and Koch has exercised a greater influence on Japanese medical thought and work than any other man. Bacteriology and laboratory methods occupy a predominating position and nearly all the Japanese medical scientists whose names are known throughout the world are bacteriologists or laboratory workers. The laboratories of Japan are numerous and well equipped and thousands of young men are eagerly engaged in experimental work; the clinicians find themselves in a position of relative unimportance and the wards are usually the least satisfactory parts of the hospitals. There is no movement towards resuscitation of the obsolete indigenous system of medicine, such as is seen in India; modern science is pursued with as great eagerness as in any other country in the world.

Medical scientists occupy a high position in the social and official world of Japan; Baron Kitasato is an honoured member of the House of Peers and it is common for men belonging to the highest families in the land to adopt medicine as a calling. In Japan as in Germany it is not considered derogatory for medical scientists to co-operate in the commercial side of medicine; some of the leading research institutes are said to make a large income from the sale of vaccines and sera and the laboratory worker appears to have better prospects of a lucrative career than the physician or surgeon. This, however, can hardly be a full explanation of the enthusiasm with which so many young men take up research work, there is evidence of a strongly developed spirit of scientific curiosity and of a desire to achieve experience in scientific work. It is remarkable that a country which has so recently adopted science should already have produced so many men whose names are honoured in bacteriology and pharmacology, and although Kitasato drew his inspiration from Koch and Hata from Ehrlich there is now a well established Japanese school of medical investigation. The handicaps under which the Japanese students work should not be forgotten; one of the leading business men of Osaka assured me that the difficulty of the Japanese language was such that it involved a wastage of about three years of the average student's life as compared with the time that is occupied by western students in acquiring a mastery of their own language.

The necessity for the laborious study of at least one European language is an added handicap which is greater than that of the Indian student who learns English, and is far greater than that of the European student who acquires another modern language. The Japanese have no special aptitude for languages and so our admiration is unbounded for those who acquire a good working knowledge of English and German as well as of their own very difficult language. English is compulsory in the higher schools, but the time is yet distant when the knowledge of English will be as universal among educated Japanese as it is among educated Indians.

Considering the reputation of the Japanese for meticulous accuracy, it is surprising to find that a low standard of correctness in spelling and grammar exists; English school books, readers, dictionaries and advertisements are full of mistakes which could have been avoided by enlisting the help of a foreigner or even of a highly educated Japanese. Some Japanese-managed newspapers are published in English; in these mistakes are few unless one considers it a mistake to adopt Americanisms in a lavish manner. American influences are far stronger than English in commerce and in games and the Tokio press reports of baseball matches would do credit to a Chicago evening paper.

Japan is engaged in a strenuous effort to deal with her great medical problems on scientific lines, she has earned the admiration and sympathy of the whole world, their help she is too proud and too self-reliant to crave. Japan has deliberately broken with her past and has started on the path of modern progress. Only one doubt persistently creeps in, how will she deal with the problem of population and food supply? Increased production and improved physical efficiency are the methods which are being relied on and it is reasonable to hope that these will suffice for a time. The average age of men on marriage has advanced by a few years and is still slowly advancing, but the Japanese refuse to contemplate for an instant the adoption of a policy of restriction of the population. If the present rate of increase is maintained the critical period cannot be staved off indefinitely, but the problem is one which the Japanese hardly discuss among themselves, still less are they prepared to discuss it with outsiders. Their problems of disease on the other hand are discussed with absolute frankness; tuberculosis is the greatest scourge in Japan, just as it is in the other countries of the East: venereal disease is exceedingly common in spite of the elaborate methods of official inspection of the licensed prostitutes of whom there are more than three hundred and fifty thousand; beriberi appears to be on the increase and although it does not rank high as a cause of death it is

certainly one of the great factors in producing disablement and loss of physical efficiency.

The medical men who, like myself were the guests of the Japanese Government at the Sixth Congress of the Far Eastern Association of Tropical Medicine in October last, were unstinted in their admiration of the marvellous capacity for organisation and of the unbounded hospitality which they received wherever they went. The Seventh Congress of the Association will be held in India in 1927; we cannot for a moment expect to maintain the high standard of hospitality which was set by Japan. India will have to make a great effort to avoid the "odious comparisons" which will inevitably be made if the foreign delegates find that their treatment is in marked contrast with what they received in Japan and the other countries in which the Congress has previously been held.

There should be no difficulty in making the scientific side of the next Congress a success, the number of papers will probably be much less than at Tokio, but for that very reason there should be greater opportunities of discussion, and for learning from the foreign delegates who will attend.

Japan is an ideal country for a brief holiday, and the visitor who goes there in quest of recreation or for the study of art will not be disappointed. One piece of advice will be found useful by the foreigner, he will be well advised to mind his own business and to avoid the patronizing attitude which some visitors affect. The Japanese are both proud and sensitive, they regard it as their own duty to deal with the problems which confront them and they resent the gratuitous advice of the foreigner, however well meant it may be. Nobody can complain of their adoption of this attitude, the Japanese themselves are strictly correct towards the people of the countries which they visit, they ask numberless questions and seek for information with great diligence but they do not meddle in the internal affairs of other countries. We hope that Japan and other countries of the East will be well represented in the next congress of the Far Eastern Association of Tropical Medicine, but we must ask the delegates to be indulgent towards the efforts of India to entertain them. They will receive a warm welcome and for the sake of the good name of India it is to be hoped that they will not have reason to complain of the hospitality which will be extended to them. The Government of India doubtless realise that a great effort lies before them if the seventh congress is to be a success, but it is necessary also that the Local Governments and the medical profession of the places which will be visited should bestir themselves to give their guests a pleasant and profitable time during their visit to India.

Report on the Student Welfare Scheme for the year 1924. (Health Examination of College Students of the University of Calcutta.)

THIS year's report covers the examination of 9,056 students, examined up to 31st December 1924. The percentage of Hindu students is as high as 85, while that of the Mahomedans is 7 only though Mahomedans constitute 53.55 per cent. of the population of Bengal.

Among the Hindus, the Brahmins, Kayasthas and Baidyas described in the Census as the *bhadralog* classes claim 66.5 per cent. of students. About 7.5 per cent. show good muscular development and 27.5 per cent. are of thin build. The remainder are described as stout or medium.

This year's record shows a fall of about 6 per cent. in the number of students having defective skins. Under defective skins are included all sorts of skin diseases. Acne and scabies are the most common forms of skin troubles. Nearly one-third of all the students suffer from some form of skin-disease.

The following table shows height and weight according to age.

Fifty-Five Years of Progress in Surgery.

By Sir ARTHUR MAYO-ROBSON, K.B.E., C.B., C.V.O., D.S.C., F.R.C.S.,

Emeritus Professor of Surgery in Leeds University, and Consulting Surgeon to the Leeds General Infirmary.

British Med. Jour., October 10, 1925.

I FEEL it a great honour to have been asked to give the opening address of the Medical Department of the Leeds University.

To-day is the fifty-fifth anniversary of my entering as a student, and, with short intervals for post-graduate study at home and abroad, it was my privilege to be attached, in one capacity or another, to my Alma Mater for over thirty years before making London my centre. I had the good fortune to begin my life's work in 1870, when there was great advantage in witnessing and taking part in the old order of things and being able at once to appreciate and participate in the reformation that came within the next few years of seeing the birth and growth of the science of bacteriology, the key that unlocked the way to the knowledge of the cause of so many diseases, of taking part in the infancy, the adolescence, and the sturdy manhood of its brilliant offspring antiseptic and aseptic surgery and of having the honour of making a personal acquaintance with, and of being an ardent disciple of, those two great masters—Pasteur and Lister. To those of my audience who are entering on their medical studies to-day, and to any other students who have not read them, let me recommend two books, which will not only give you the greatest pleasure to read and carefully study, but

which will stimulate you in your careers and afford you great examples to live up to. They are: (1) *The Life of Pasteur*, by his son-in-law, René Vallery-Radot, which I read when first published in the original, but which I have read a second time, with equal interest, in a very good translation by Mrs. R. L. Devonshire, with an excellent introduction by my late distinguished friend Professor Osler. (2) *The Life of Lord Lister* by his nephew, the late Sir Rickman Godlee, for some time a colleague of mine on the Council of the Royal College of Surgeons, and later President, who was himself a distinguished surgeon.

In the early seventies, it was possible to see hospitals ravaged with hospital gangrene, septicæmia, and pyæmia; when any operation however simple, might, and frequently did, assume complications of the most serious import, often ending in death. For instance, I actually saw death follow the simple tapping of a hydrocele by an eminent surgeon. Secondary hæmorrhage was of frequent occurrence, and it was usually considered advisable to have tourniquets at hand or even around limbs, ready for the attendants to tighten up when the silk ligatures were due to separate. Ordinary compound fractures often ended in loss of life or limb or took weeks or months to heal, and not infrequently ended in shortened or crippled limbs. Erysipelas, pyæmia, septicæmia, and tetanus were never long absent from surgical wards. Erysipelas was explained by change of weather, tetanus by nerve irritation, tubercle by a diathesis, and rapid deaths from septicæmia by shock. Abdominal diseases were treated expectantly, practically always; and if we refer to the hospital reports of the very few cases operated on in the large London and provincial hospitals, we shall see that it was a wise provision that such cases were handed over to the physicians by universal consent. They considered the adoption of palliative measures and the making of a diagnosis quite adequate, until Nature relieved the victims and enabled a confirmation or otherwise of their surmises to be made on the *post-mortem* table.

Soon after receiving my qualification in 1874, I was asked by a medical man if I would go to Glasgow to be present at an operation—amputation of the thigh for senile gangrene—about to be performed on a relation of his, by a general practitioner. The doctors arrived with two large stone bottles of whisky, which was poured into several washhand basins. Into one were placed the instruments and silk ligatures, into another sponges, and into another dressings, while another served for soaking the hands of the surgeon and washing the patient's thigh at the line of amputation. The limb was amputated expeditiously and well; the vessels were ligatured with fine silk, the ligatures being cut short; the face of the stump was well sponged with pure whisky and the flaps were sutured, the stump being closed without drainage. Fine towels, wet with whisky, were placed over the stump so as to make a complete and well padded dressing, which was then bandaged on and supported by a short splint. The patient made a complete recovery, and the wound healed by first intention.

Thus I saw my first perfect aseptic—or should it be called antiseptic?—major operation, which made a great impression on my mind and served me as an example for many subsequent successes.

Although between 1867 and 1869, 34 out of 40 amputations had survived in Lister's wards, his isolated voice was not attended to, and not even his celebrated lecture in 1870 on "The utility of antiseptics applied to surgical practice" received the attention it demanded. It is sad to think of the thousands of young men who perished in the ambulances and hospitals of France in 1870 and 1871, who might have been saved by Lister's method. But the heads of the profession in France took no interest in the rumours of the success being attained by antiseptic methods; and even in his own country Lister's method was violently criticized and turned down. This opposition continued year after year to my knowledge, and even pursued Lister when he was appointed surgeon

to King's College, London, where some of his colleagues on the staff were his bitterest opponents. As an ardent disciple, I had the advantage of following his work, as to the value of which I had had no doubt from the time I began my surgical studies and became acquainted with the doctrines of Pasteur and Lister.

Even in the early eighties, when I had the honour to be appointed honorary surgeon to the Leeds General Infirmary, my distinguished predecessor handed me with pride and with some ceremony his operating coat, which he was still using, and which he had used for years; it was covered with innumerable spots of old clotted blood. I began my work by wearing washable garments frequently changed, and when requesting the same for my assistants and nurses the question of laundry expenses was raised. At a later stage, when initiating the wearing at all my operations of boiled rubber gloves, on the advent of aseptic in place of antiseptic surgery, the complaint of extravagance was even more strongly urged, and was only settled, as time wore on, by the results, which compelled their general adoption.

On taking up my appointment on the staff of the infirmary, abdominal surgery was practically confined to ovariectomy, of which the mortality was 26.6 per cent.

At first, using antiseptics as advocated by Lister (which, although they kill the germs, at the same time damage the tissues), I became more and more impressed with the value of asepsis, or absolute cleanliness, which avoids the introduction into wounds of any germs, thus rendering the use of strong poisons, such as carbolic acid, unnecessary. Metchnikoff's researches, which showed the phagocytic power of the white corpuscles in wounds, enabled the presence of the very few organisms in the air to be ignored, if every care was taken by the surgeon not to introduce any by hands, instruments, sponges, or dressings.

In 1889 I published a list of all my abdominal operations from the time of beginning my work in the infirmary. This paper was read at the meeting of the British Medical Association in Leeds in August, 1889.

There were 61 ovariectomies with only two deaths, equal to 3.2 per cent.; 12 cases of cholecystotomy for gall stones and 1 of cholecystenterostomy without a death; 28 cases of radical cure of hernia, 6 cases of pelvic abscess, 5 cases of tuberculous peritonitis, and 2 cases of hydatid cyst of liver, all without a death; 30 cases of strangulated hernia with 5 deaths, all from gangrene or rupture of the intestine, but none from wound complications; 14 cases of operation for myoma of uterus, including hysterectomy, with 3 deaths; and 15 operations for malignant disease too extensive for removal, and cases of general peritonitis from ruptured viscera, with 9 deaths.

This list serves to illustrate the great advances that had been made in abdominal surgery up to 1889.

On June 21st, 1884, I performed my first operation for gall stones, and began to devote special attention to diseases of the gall bladder and bile ducts. After an experience of nearly 200 operations for gall stones, in the absence of malignant disease, profound jaundice, or infective cholangitis, with the loss of only a single patient, and even if the complications above mentioned be included, with a mortality of only 2.7 per cent., I decided to give my experience in book form, under the title of *Diseases of the Gall Bladder and Bile Duct*, including gall stones, which was published in June, 1897.

The surgery of the stomach, pylorus, and duodenum next formed a very interesting and new field of work, in a class of cases treated before the reformation of surgery entirely by the physician, with only moderate and usually temporary relief. The success of surgical treatment, which enabled the stomach to be accurately examined in the living subject, added enormously to our knowledge of the pathology, and enabled us to put in practice a number of new operations or more efficient modifications of older ones. After an experience of over 200 gastric operations, I was again elected Hunterian Professor at the Royal College of Surgeons in 1900, and took as my subject for the lectures *Diseases of the*

Stomach and their Surgical Treatment. As no work on gastric surgery had been published, and as much new and original material had accumulated for the purpose, I decided to write a work having the same title as the Hunterian Lectures, on which in fact it was based. I was fortunate in securing the help and collaboration of my colleague and former house-surgeon, Mr. Berkeley Moynihan, now your distinguished Professor of Surgery, Sir Berkeley Moynihan, Bt., whose brilliant career has been a source of great pride to us all, and to me especially, since we were intimately associated when he was appointed assistant surgeon to the infirmary. Our first edition was published in 1901, and a second edition in June, 1904, when we were able to report an experience of 218 posterior gastro-enterostomies in simple diseases of the stomach, with a mortality of 3.2 per cent., a great contrast with the year 1885, when the mortality from all sources was 65.71 per cent., whereas in 1890 it was 47 per cent. and in 1900 35.4 per cent.

After the accumulation of considerable experience in operations on the pancreas, I had the honour in 1904 of being appointed for the third time Hunterian Professor at the Royal College of Surgeons, taking as the subject of my lectures "The pathology and surgery of certain diseases of the pancreas." These were subsequently published, along with numerous additions, in a work entitled *Diseases of the Pancreas and their Surgical Treatment*, in which I again had the collaboration of my colleague Mr. Berkeley Moynihan. During the whole time of my work on the pancreas I had had the valuable help, in various chemical and pathological questions constantly arising, of my friend Dr. P. J. Cammidge; in 1907 we published a work together, dealing largely with the pathology of the pancreas.

My first of many hundred operations for appendicitis was on June 8th, 1891, and to mark the progress and success of surgical treatment it is only necessary to refer to the infirmary reports for 1885 and 1925; in the former appendicitis is not even mentioned, whereas in the latter 788 operations are recorded, with a mortality of only 3 per cent. Of intestinal surgery there was mentioned only one operation in 1870, whereas in 1925 there were 180. Of renal and ureteral surgery there is no recorded case in 1870, but 85 operations are reported in 1925.

In 1874, when attending a course of lectures on mental diseases at the Wakefield Asylum, given by Dr. (now Sir) James Crichton-Browne, I had the privilege of witnessing demonstrations on the localization of the functions of the brain, given by Dr. (now my distinguished friend Sir) David Ferrier, whose remarkable discoveries, along with those of Dr. Hughlings Jackson, rendered possible the subsequent brilliant work of the late lamented Sir Victor Horsley, who gave his life for his country in the great war.

The descriptions of the evacuation of localized abscesses of the brain, of the treatment of Jacksonian epilepsy, of the removal of cerebral tumours, of the extraction of bullets and other foreign bodies, and of many other operations, would sound like a romance did time permit of a description.

Fractures.

The treatment of simple fractures, some by wiring the bones, from the first cases of fracture of the patella wired by Lister to the more frequent wiring of other bones by my friend Sir Arbuthnot Lane, and the innumerable cases of compound fracture, especially of the femur, treated by Thomas's splints and other special appliances, and with an infinite care in dressings, have completely revolutionized this branch of surgery, leading to the saving, during the war, of many thousands of lives and limbs that must otherwise have been lost.

The enormous amount of valuable orthopaedic work done during and after the war in the various war hospitals, chiefly under the direction of that master of orthopaedic surgery, Sir Robert Jones, has resulted in a great saving of deformities among wounded soldiers. The importance of orthopaedics in civil life is shown

by the valuable work of the orthopaedic department in the Leeds Infirmary, in which no fewer than 910 operations are recorded in 1924.

Surgery of the Prostate.

The operation of prostatectomy initiated and carried to perfection (as shown by specimens in the museum of this Medical School) by my late colleague and friend, Arthur Fergusson McGill, one of the surgeons to the infirmary, whom to know was to love, has been of infinite service in prolonging life and adding to the comfort of thousands of elderly men, the remainder of whose lives would otherwise have been one of torment and sorrow. Had that great surgeon been spared to work for a few more years, I feel sure that his skill as a surgeon and his original and fertile mind would have been of still greater service to the profession and to mankind generally. It seemed to some of us very hard that the reward of his labours should have fallen to others; but fortunately the operation was taken up later, where he left it, by the late Sir Peter Freyer, in whose able hands it was carried out so successfully that in 1912 he reported in the *British Medical Journal* 1,000 operations of complete prostatectomy.

In bone injuries and diseases; in the discovery of calculi in the kidneys and ureters as well as in the pancreas and bile passages; in the localization of foreign bodies in the heart, the lungs, the œsophagus, the stomach, the intestines, and in various parts of the body; in the diagnosis of diseases of the stomach and intestines by observing the passage of bismuth test meals; in observing the size and pulsations of the heart, and in many other ways, both for diagnosis and treatment there is now in every well equipped hospital an x-ray department, in which much valuable work is being carried out by experts in this new branch of medical practice.

Pasteur's Influence on Medicine.

The influence of Pasteur's work in medicine has been no less than Lister's work in surgery; for the germ theory of disease has led to a knowledge of the causes of the various infective and many other diseases, and by means of vaccination or protective inoculations to the prevention or relief or cure of many of them; for instance, tetanus, diphtheria, typhoid fever, cholera, splenic fever, malignant pustule, hydrophobia, staphylococcal diseases, such as boils, carbuncle, osteomyelitis, and acne; and some of the streptococcal infections. In the war many thousands of lives were saved by the preventive injections of antityphoid vaccine, with which we were all inoculated before going out to the front, and by the injection of antitetanic serum into every wounded soldier on the battlefield before reaching the casualty clearing station.

In obstetric medicine the influence of Pasteur's teaching, and his bold exposure of the carrying of puerperal infection by the direct conveyance of germs through dirty hands, instruments, and dressings of those attending the lying-in woman, brought about such a change in the death rate as to appear almost miraculous. The saving of life has been almost as great as that brought about by the antiseptic system in surgery. Puerperal fever, that terror of the lying-in woman, has been practically abolished. For instance, in the maternity department of the Leeds Infirmary during 1900 there were 547 women delivered without a single maternal death.

Of Pasteur's many other discoveries and victories there is no time to speak, but I ask my audience, Was there ever such a benefactor, not only to his country, but to humanity in general and to the world at large? His life rings with the spirit of service.

Conclusion.

In the time at my disposal I have tried to show the immense progress that has taken place in surgery during the past half-century. I have also tried to show what a close connexion exists between the science and art of our profession, and how very necessary it is, if we are

to continue our march of progress, that experimental research should not only be untrammelled by factious and unreasoning opposition, but that it should receive greater recognition, encouragement, and support at the hands of the public. An even closer alliance between the physician, the surgeon, the pathologist, the bacteriologist, and the physicist is desirable, as the time is coming when preventive measures, some of which I have portrayed, will save much operative work, and when it will be thought a greater triumph to prevent than to cure disease.

It is quite evident that methods which were considered sufficient years ago are totally inadequate to-day. We may modify but we cannot prevent the world's advance; and while times change men change with them. The medical profession is imbued with a spirit that half a century ago was undreamed of. Not only have apparently insurmountable difficulties been overcome, but habits of thought have been attained which have made such achievements possible, and a scientific attitude of mind has become characteristic of our profession, as it has of the leaders in every branch of the world's progress.

Acute Intestinal Obstruction.

British Med. Jour., November 28, 1925, p. 993.

At a British Medical Association meeting the discussion was opened by Sir William Taylor, Regius Professor of Surgery, Dublin University.

The mortality attending the treatment of this condition is not one whit better to-day than it was at the beginning of the century. This appalling state of affairs is solely due to carelessness of the general practitioners or physicians who see these unfortunate cases in the earlier stages of their illness. Instead of recognizing that purgation and enemas can do no good, but on the other hand, may do an infinity of harm, these practitioners are continually laying themselves open to an action at law for malpractice.

The mortality attending the surgical treatment of primary acute intestinal obstruction, the result of intra-abdominal conditions is nearer to 60 per cent. than the 35 to 40 per cent. usually stated—a truly shocking state of affairs.

Apart from acute intussusception, three stages can be recognized in these cases, and the treatment must necessarily vary according to the stage in which one finds the patient.

The first stage is that in which the patient is seen early (within twenty-four hours). His general condition is good and there is but little intestinal distension. The second stage is that in which the patient is not seen until later—two, three or four days. His general condition is good, but there is considerable intestinal distension and severe vomiting which may or may not be stercoraceous. The third stage is that in which the general condition of the patient is bad. His pulse is feeble and perhaps intermittent, and vomiting is almost continuous and is certainly stercoraceous.

The treatment of the first stage consists in washing out the stomach with sodium bicarbonate solution. A general anæsthetic is administered and the abdomen is freely opened. The cause of the obstruction is searched for and removed, after which the abdomen is closed. The stomach is again washed out and the patient returned to bed. Lavage of the stomach after operation is more important, in many cases, than it is before the operation.

In the second stage a similar procedure is adopted until the obstruction is discovered and removed. A separate incision should then be made through the left rectus muscle above the umbilicus, and a loop of the jejunum, as close to its origin as possible, is brought out through the wound. Into it is fastened a tube of 7 or 8 mm. diameter, after the method of Senn's gastrostomy, except that only one or two purse-string sutures are used, so that too much subsequent narrowing

of the intestinal lumen may be avoided. The intestine is then returned within the abdomen and fixed with two catgut sutures, one on each side of the tube, to the parietal peritoneum and posterior sheath of the rectus. A lunate piece is cut out of each side of the end of the tube before it is introduced into the intestinal opening, so that if it should accidentally impinge upon the opposite wall of the bowel the intestinal contents could still escape freely. By this procedure the distended intestines will be allowed to empty themselves of their poisonous contents. The central wound is then closed. The stomach is thoroughly irrigated as before, and the patient put back into bed. An experienced nurse or a senior student is directed to continue irrigating the intestines with sodium bicarbonate solution by siphonage through the tube. In this way, without taxing the patient's strength and without producing any shock, the intestines are assisted to empty themselves. This process can be continued for several hours, at the end of which time the entire intestinal area between the stoma into which the tube has been introduced and the point at which the obstruction existed will have been emptied of its contents, and these contents replaced in large measure by a fluid containing sodium bicarbonate and glucose, the absorption of which will counteract the tendency to acidosis and help to build up the reserve carbohydrates as well as replace the fluids of which the tissues have been deprived by the continuous vomiting.

In the majority of these cases the tube can be removed in twenty-four or forty-eight hours under gas or local anæsthesia. Lactose may be given freely either by mouth or through the intestinal tube, as it has been shown that lactose can eliminate proteolytic bacteria from the intestinal flora.

In the third stage the patient is too ill to stand the administration of a general anæsthetic, and he is not even removed from the bed in which he lies. The stomach is washed out as described above, after which the tissues of the abdominal wall above the umbilicus are infiltrated with a $\frac{1}{2}$ per cent. solution of novocain. An incision of $1\frac{1}{2}$ or 2 inches is then made through the middle line or left rectus muscle, as may be desired, into the abdomen. A finger is introduced and a loop of the jejunum, as near to its origin as possible, is withdrawn. A tube is then introduced into this fluid-containing segment of gut as before described, and siphonage similarly continued.

Should the patient survive, it may be possible at the end of a week to open the abdomen, seek out the cause of the obstruction and remove it. In the meantime nourishment can be administered through the tube directly the intestinal contents have been evacuated, or it may be given by mouth. The tube must not be removed until the patient has recovered from the effects of the second operation.

In all cases of intestinal obstruction in which stercoraceous vomiting has occurred, drainage of the jejunum as close to its origin as possible should be instituted. This drainage can be assisted by repeatedly filling up with sodium bicarbonate solution and siphoning off the intestinal contents after the patient has been returned to bed.

The treatment of acute obstruction engrafted upon chronic is somewhat different. The site of the chronic obstruction will almost invariably be found to be somewhere in the large intestine, and in all such cases the bowel above the obstruction should be drained at once. A cræcotomy after the method of Sir Harold Stiles gives the best results so far as tiding the patient over his immediate dangers is concerned. This carries out Bonney's idea of draining the fluid-containing segment.

Of the mechanical conditions producing primary acute intestinal obstruction within the abdomen intussusception is the commonest I have myself encountered. There is no acute abdominal condition more easy to diagnose, and that, too, although the majority of such cases are met with in young infants who are unable to speak. There cannot be any excuse for failure to recognize this condition within from an hour or two to twelve hours

after its onset. The condition is met with most frequently in infants between the ages of 2½ months and 10 or 12 months—my youngest case occurred in an infant of 2½ months. It is occasionally met with (but with diminishing frequency) at all ages up to 70 or more.

The diagnosis of intussusception once made, the only satisfactory method of treatment consists in early operation and reduction by gentle expression from below upwards. Care should be taken to see that the least dimple at the site of commencement of the intussusception is expressed.

Recurrence is rare. Sir William's mortality has been 3 deaths in 81 cases. For some years past he has sent these cases home a few hours after they have recovered from the effects of the anæsthetic. The mother reports daily to the hospital as to the infant's progress or a student visits the case.

This condition requires great gentleness in manipulation and great rapidity in operating. Given an average care of less than twenty-four hours' duration the complete operation should not require more than ten or eleven minutes to perform.

Mr. W. Sampson Handley, Surgeon to the Middlesex Hospital holds that if diagnoses were made and operations were skilfully performed within twenty-four hours of the onset of acute obstruction, it is certain that recovery would ensue in nine cases out of ten. The textbooks are confused and deficient in the information they supply. They usually give a complete list of the signs and symptoms of obstruction, but they make little distinction between the valuable early signs and those which merely mark a lost opportunity. The early signs are few and some are inconstant, the signs of shock and collapse may be entirely lacking if strangulation is absent. There is usually no distension, and the muscle of the abdominal wall is perfectly soft; even pain and vomiting are not invariable signs.

To make an early diagnosis the observer must rely exclusively upon the presence of complete constipation—that is, cessation of the passage of flatus and fæces for a period of twenty-four hours, during which time two turpentine enemas are given.

Secondary paralytic obstruction is sometimes the result of strangulation, and persists after the strangulation is relieved; or is sometimes due to the extension of peritonitis to the muscular coat of the bowel.

There are cases where a loop of bowel has been released from strangulation, and where its condition appears recoverable and resection unnecessary, or forbidden by the patient's age and general condition. Unfortunately in some of these cases, though gangrene of the strangulated loop does not supervene, the loop nevertheless remains paralysed, and the patient dies of obstruction before the affected loop has recovered its peristaltic power.

Mr. Sampson Handley urges the performance of a precautionary lateral anastomosis to short-circuit for the time being the doubtful loop.

The Prevention of Squeezing in Cataract Operations.

DR. F. KUGELBERG of the Swedish Mission Hospital in Tirupatur, has an interesting article on this subject in the *Journal of Medical Missions in India* for November, 1925.

The principle adopted is nerve blocking as suggested by van Lint in 1914 and followed up by Villard and Major Wright of Madras. Dr. Kugelberg now employs a method of nerve blocking in every case. A 2 per cent. solution of novocain is used and to each c.c. one drop of 1 in 1000 adrenalin is added. A 2 c.c. "Record" syringe is fitted with a fine needle of rustless steel (B. & W. No. 213 about 3.5 cm. long). The eye is treated with 5 per cent. cocain to each c.c. of which 4-5 drops of adrenalin solution are added and then the muscles of the forehead and eyelids are thrown out of action by blocking the facial nerve and the nerves of the eyelids in the

manner described by the author. The operation is begun after 20 minutes when the maximum effect is produced. The paper should be read by all eye surgeons.

Röntgen Ray Treatment of Cellulitis and Carbuncles.

DR. FRED M. HODGES of Richmond, United States of America reports in the *Journal of the American Medical Association* of October 24th, 1925 several cases in which great success followed the use of x-rays in the treatment of carbuncles, erysipelas, parotitis and various forms of cellulitis. The technique used in most cases: 4 milli-amperes; 9 inch spark gap; eight minutes; 9 mm. of aluminium; 9 inches distance; half this dose was repeated in four days and several days later when necessary. The area treated included one inch of healthy skin all round at the first sitting; later treatments were directed towards the central lesion.

Race Suicide in Kashmir.

ACCORDING to Dr. Kathleen Vaughan the Hindus of Kashmir are diminishing in numbers at the rate of about 1,000 a year, although they form the ruling and intellectual classes of the country. The reasons given are venereal disease, tuberculosis, osteomalacia and infanticide. It is stated that many "unwanted" infants are strangled or drowned soon after birth.

It is difficult to believe that infanticide should prevail among a notably cultured section of the community in Kashmir.

The Treatment of Tuberculosis in General Practice.

By G. Y. OLIVER, B.A. (Cantab.), M.R.C.S.
The Prescriber, August 1925.

THE greatest problem in the treatment of tuberculosis is undoubtedly early and accurate diagnosis.

One of the most important signs of early tuberculosis is the drop in the blood pressure. A blood pressure below 90 mm. is suspicious.

The most reliable and earliest sign is that of Pottenger, who has shown that inflammatory changes in the lungs give rise to sensitiveness on the areas of skin served by the second cervical to the tenth dorsal nerves. A very fine needle is drawn over the skin in horizontal lines, the patient being asked to say when it feels more tender at one point than another. It is surprising how early the sign appears; it can be obtained even before the temperature starts to rise.

The patient suffering from incipient tuberculosis feels slightly languid; he has no night sweats, no cough, and perhaps a rise of one degree in the evening temperature twice in one week; has a blood pressure of 90 mm. (danger sign) and has also a slight area of superficial tenderness over the apex, either in front or behind, sometimes it may be both back and front. A very few crepitations are found over this area, and on being skiagraphed the diaphragm on the same side as the superficial tenderness lags behind the sound side. These signs are confirmed by injecting Crofton's 'H.T.S.' antigen* under the skin. This is a solution of the entire tubercle bacillus in benzoyl chloride, including the fatty envelope lipoids, and is the most perfect preparation of antigen possible.

Start with the smallest dose first 0.000,000,1; if there is no reaction give 0.000,00,1; if still no reaction give the next in the series 0.000,01. It is extraordinary how some bad cases do not react until one reaches a fairly high dosage, whilst cases which one would have no suspicion of develop an alarming reaction after the first

* Crofton's antigen ("H. T. S." or Human Type Solution) was described in *THE PRESCRIBER*, 1924, Sept. 316. A full account of it may be found in Dr. W. M. Crofton's work, "Pulmonary Tuberculosis" (Churchill, 1917).

injection. The patients take their temperature every two hours during the forty-eight hours following the injection. In some people the reaction seems to be delayed for 36-48 hours.

1. *Local Reaction.*—This may appear as a very faint erythema, or may go on to an acute inflammation, which may even spread all over the arm. In nearly all these cases one notices a hard lump at the site of the injection, which may be from the size of a pea to that of a horse-chestnut. These hard nodular swellings persist for nine or ten months; in consequence of this it is advisable to inject in a different part of the body each time, and if the lesion is only one-sided, it is important to avoid the arm of that side altogether.

2. *General Reaction.*—This is simply a feeling of malaise, with rise of temperature and pulse rate. The patient must be advised to go to bed when the temperature is over 100° and to stay there until it comes down.

3. *Focal Reaction.*—This reaction is very interesting to watch, and the rule holds good that whenever there is even a very slight general reaction there will also be a focal reaction in some part of the body.

In cases which give a positive reaction with Crofton's antigen, it is best to get the sputum examined to see if there is a mixed infection. If this is the case, an autogenous vaccine should be prepared and given first until the sputum contains only tubercle bacilli. In the very early cases the infection appears to be true tubercle and no other organisms are present. If the reaction is very severe, the safest plan is to wait seven days and then give the same dose again and continue to do this until the reaction is slight. The rule always should be to make haste slowly; if in the least doubt, repeat the same dose rather than give the next in the series; also great care must be exercised on changing from one dilution to the next.

Marked improvement in weight, blood pressure, and temperature is seen in all cases treated with Crofton's antigen.

The antigen appears to effect a lasting cure, as patients, six months after treatment is finished, still retain a normal blood pressure of 120 mm.

As far as one can see, all conditions of tuberculosis can be cured with this antigen, but it is quite impossible to replace the lung tissue which has been destroyed, and it is advisable to point out in advanced cases that patients must govern their activity in accordance with their lung capacity and must remember that instead of two lungs they may possibly have only one.

The Causation and Prevention of Rickets.

By A. WEBSTER and LEONARD HILL.

British Medical Journal, May 23, 1925, p. 956.

THIS very important paper gives a useful summary of modern work on rickets and contains a record of further valuable experiments. We give some of the more important facts recorded in the paper.

Rickets is so frequently found in the large cities of America and Europe that it is doubtful whether the children of the poorer classes ever wholly escape it. It reaches its height in the winter and declines in the summer. Palm was the first to correlate this seasonal variation with the incidence of sunlight, and thus to anticipate by many years wider discoveries.

Mellanby in 1918 concluded that rickets was really a deficiency disease and that the particular vitamin concerned was vitamin A or something closely associated with it. He found generally that fats richest in vitamin A were the most potent in preventing rickets, cod-liver oil being by far the best.

Soon after the publication of Mellanby's work the American investigators, McCollum, Simmonds, Shipley and Park, and Sherman and Pappenheimer, showed almost simultaneously and independently that rickets could be produced in the rat by diets that were abnormal in their inorganic constituents. They found that rickets

could be produced by diets poor in phosphorus or in calcium, or by diets that contained these elements in unbalanced amounts. More especially was it shown that a diet with a minimum amount of phosphorus could be made a ricket-producing one by the addition of excess of calcium.

Sherman and Pappenheimer proved that soluble inorganic phosphates were most efficient in preventing rickets. The specific action of cod-liver oil in curing and preventing human rickets has been established by many observers. McCollum, Simmonds, Becker, and Shipley proved that the antirachitic substance was distinct from fat-soluble A vitamin. McCollum treated cod-liver oil by combined heat and oxidation until it had lost its power to promote growth; this oil was found, nevertheless, to be potent as an antirachitic agent. This settled once and for all the non-identity of vitamin A and the unknown antirachitic agent.

In 1919 the German physician Huldshinsky reported that he had cured cases of rickets in children by radiating them with the light of a quartz mercury vapour lamp. The action was not local, radiation of one limb healing the rickets of both limbs.

It was proved that the active rays were the short invisible ultra-violet rays. Window glass cuts off these rays. Hess and McCollum showed that the rays of the sun would prevent rickets in rats. If the sunlight is filtered through glass then it does not protect against rickets.

Radiant energy is as important a factor in the cure and prevention of rickets as the unknown substance present in cod-liver oil and other oils. The blood in cases of rickets is low in inorganic phosphorus. The inorganic phosphorus of normal children is about 5 mg. per cent.; in cases of rickets it may fall as low as 1 mg. per cent. Palm many years ago expressed the opinion that rickets is due to insufficient sunlight.

It is well established that rickets is a metabolic disease characterized by bones deficient in calcium phosphate and accompanied by a diminished content in the blood calcium and of inorganic phosphate; that it can be cured both clinically and in experimental animals with certainty by administering cod-liver oil; and that the curative action is not due to vitamin A. It can also be cured with certainty by the action of ultraviolet light. The experiments of Webster show that experimental rickets is accompanied by defective absorption of calcium and phosphorus from the intestinal tract and a very low uptake of these elements from the food supplied.

Other observers have found that this is also the case with rachitic infants. These results suggest very strongly that the primary seat of rickets is the gastrointestinal tract. It has been suggested that the bacterial flora of the intestine may have some influence on absorption but Korenchevsky was unable to produce rickets experimentally by bacterial means. Findlay suggests that the digestive processes are impaired in rickets and quotes some experiments that support this view. The diets used for the experimental production of rickets do so by virtue of their deficiency either in quantity or in balance of calcium and phosphorus, and if this is rectified, then the animals do not develop rickets even if they are deprived of vitamins and radiant energy.

McCollum took rats which were rendered rachitic and starved them for a few days and then killed them. The period of starvation was followed by a marked deposition of lime salts. The break-down of the starving animal's tissues liberated phosphorus and calcium, which were promptly used to build up bone. This tends to show that it is not the rachitic animal's power of forming bone which is at fault, but lack of the raw materials—that is calcium and phosphorus.

A consideration of the evidence given in this paper strongly suggests, then, that the primary cause of rickets is a low calcium and inorganic phosphate level in the circulating blood, and that this is due to defective absorption from the intestinal canal.

By experiments carried out on rats fed on			
Patent flour	..	95	grams
Calcium lactate	..	2.9	"
Ferric citrate	..	2.0	"
Sodium chloride	..	0.1	"

phosphorus starvation was caused and the diet never failed to produce rickets. The following results were obtained—

(1) Confinement *per se* was not found to be responsible for the development of rickets.

(2) A minimum exposure of two hours to bright sun or sky-shine five days a week was necessary to protect rats from rickets under the severe experimental conditions.

(3) The minimum exposure to ultra-violet rays that will prevent rickets was found to be five minutes daily, two feet from the mercury vapour lamp, and about thirty minutes for the carbon, at the same distance.

(4) Rickets was not produced in rats fed on a normal diet and subjected to a high temperature for twenty-eight days.

(5) Providing the diet is adequate, conditions simulating the tropics at their worst, but without any ultra-violet light, will not give rise to rickets in young rats.

(6) Rats fed on rickets-producing diet and exposed to dry heat were given thirty minutes exposure to the carbon daily; none of the rats showed any signs of rickets.

Provided an animal is supplied with food just sufficient to maintain life and a little growth, and a bare minimum of the bone-forming elements calcium and phosphorus, then if ultra-violet light be supplied in adequate amount rickets will not develop, however unfavourable the animal's environment be.

Sulphur can in about half the animals prevent rickets, but its action is uncertain. Magnesium sulphate and thymol proved to be useless as antirachitic agents. Arsenic had some action in preventing rickets.

A group of rats was given one hour's exposure to the mercury vapour lamp weekly, four exposures being given in all; this sufficed to protect them completely from rickets. The antirachitic body in cod-liver oil and ultra-violet light both act in the same way in preventing rickets; this mode of action is a facilitation of absorption of calcium and phosphorus from the intestines into the blood stream.

Steenbock and Black, and also Hess, have published papers claiming that rickets can be prevented in rats by radiating the diet with ultra-violet light. Rats were fed on a rickets-producing diet which was placed under the mercury vapour lamp twelve inches from the burner and radiated for half an hour; the rats showed no signs of rickets. Other rats were fed on the standard diet and in addition received 0.5 gram. daily of an inactive linseed oil that had been radiated half an hour, twelve inches from the mercury vapour lamp; these rats showed no signs of rickets.

In another experiment the patent flour portion of the diet only was radiated; the rats fed on this proved to be free from rickets. Another group fed on the standard diet, in addition received a daily dose of radiated hardened cotton-seed oil. On killing the rats at the end of the twenty-eight days they all showed, on x-ray examination, severe rickets.

These results confirm the work of Steenbock and Black, and Hess—that certain rickets-producing food-stuffs can be made antirachitic by radiation with ultra-violet light.

The Treatment of the Pneumonias.

By JOHN WISHART, M.D., D.Sc., F.L.S.

Prescriber, July 1925, p. 255.

THREE definite lines of treatment are open to us at the present day, and one of these must be adopted at the commencement of the attack. We can choose to treat our case by drugs, by vaccines, or by phylacogens. In addition, there is a treatment common to all three

which must be applied alongside any treatment selected and which may be expressed briefly as "Pneumonia Alphabet" thus:—

Avoid striking-clocks within hearing distance.

Bedclothes; extra light, with cradle.

Cheery and level-headed nurses.

Diet; nourishing and liquid; fruits, given every two hours.

Electric light, candles, or night-lights, but no gas.

Frequently spray sal volatile throughout air of room.

Give patient a 'button-hole' daily.

Hot-water bottles, not smelling of rubber.

Invalid table, travelling or movable, bedpan, urinal.

Joyfully agree to shave patient daily, if need be.

Keep patient recumbent.

Liquids to drink; abundance, especially cold water.

Magazines and newspapers: read cheering news only.

Never let patient know that he is registered as "dangerously ill."

Open windows; provide draught-screens.

Patient's garments; loose, opening at sides.

Quarter-hour increase daily in sitting-up time.

Room; quiet, sunny, fitted with dark blinds.

Sponge palms of hands and lips with cold water often.

Temperature of room 55°F.

Unnecessary movement always avoided.

Vinegar or eau de Cologne applied to forehead frequently.

When temperature normal for seven days, allow patient to sit up.

Exclude all visitors.

Yield refreshing odour by floating essence of peppermint on water in saucer below bed.

Zones of pain massaged when necessary.

It is well to start our patient off from the very first day of his illness with the following mixture:—

Tinct. digitalis.

Tinct. belladonna.

Tinct. nux vom. (ā ā 3i).

Glycerin

Infus. buchu vel scoparii ad 3vi

M. Sig.—'A tablespoonful every four hours in an equal quantity of water after food.'

Digitalis aids the struggling heart (and if given early, should prevent it from having to struggle at all), whilst strychnine and belladonna restore blood pressure by improving the tone of the vessels. A drachm of sal volatile in plenty of cold water, every three hours, is a faithful stimulant in emergency, and if cyanosis appears oxygen inhalations will be very helpful.

There is danger in allowing the temperature to run up to 105°F., and Dr. Wishart prefers to start cold-sponging patients at 104° rather than wait for 105°. He detests chemical antipyretics. Insomnia is treated by paraldehyde per rectum or orally in almond mixture and recourse may be had to morphine hypodermically, but hyoscine, sulphonal, and chloralamide should be avoided in this disease. A diuretic of an alkaline nature will keep the kidneys functioning well. The bowels cause little or no trouble if calomel at night, followed by sulphate of soda in the morning, is given at the start, and treatment followed with a suitable form of liquid paraffin.

During the crisis, the nurse should be constantly at the bedside, stimulants should be given freely, hot-water bottles should be renewed frequently, and hypodermic injections of strychnine administered as often as thought necessary.

At the stage of resolution, expectorants are of little use because the patient pants and is not trying to overcome any respiratory obstruction. Iodides are of little use, physicians are determined to prescribe them, trust is placed in a mixture of morphine with a very little ammonium chloride, along with a tonic such as sanatogen, hypophosphites, glycerophosphates, syr. ferri iodid. with glycerin, malt and cod-liver oil, or the like.

In catarrhal pneumonia antiphlogistine is applied directly to the chest before being covered with warm

cotton-wool. It should be applied on the back of the chest and up to the armpit on each side; warm camphorated liniment should then be applied to the front of the chest—even if only for the mental effect it produces on the patient. One of the most successful vaccines used in the influenza epidemic was mixed anti-influenzal vaccine (St. Mary's Hospital formula), and it was usually only necessary to give dose 1 of the three graduated doses supplied. Pneumonia phylacogen may be given subcutaneously. One c.c. of pneumonia phylacogen is given every eight or twelve hours until four doses have been given, then 2 c.c., and thereafter the amount may be increased as the conditions indicate.

The Diet in Typhoid Fever.

British Medical Journal, May 30, 1925.

V. J. KINSELLA (*Medical Journal of Australia*, February 21st, 1925, p. 183), recommends in a paper based on the study of 760 typhoid patients, a diet consisting of 2 pints of milk, 6 ounces of cream, 4 ounces of sugar, 3 or 4 eggs (in flips, custards, or boiled), 2 ounces of fish, 4 ounces of bread, and 2 ounces of butter, amounting approximately to 3,000 calories.

In spite of the anorexia so common in enteric fever, the 2,000 to 3,000 calories mark is easily reached.

Rectal Injection of Ether in Whooping-Cough.

By C. ELGOOD, B.M. (Oxford).

British Medical Journal, May 23, 1925, p. 963.

ETHER was first suggested in 1914 by Audrain, whose results were published in 1920. He used 1 to 2 c.cm. injected intramuscularly three times a day.

Mason tried ether by the rectum on four cases, using 6 c.c. of a 40 per cent. solution of ether in olive oil. Half of these were successful and half failures. Elgood is the first worker who records cases treated by ether given per rectum.

The enema is painless and the majority of children raise no objection to the repetition of the treatment. The only difficulty lies in getting a certain number of cases to retain it.

The ether was mixed with an equal amount of olive oil, the dose given being 1 drachm of the mixture for every year of age. If anything an excess was given, and if the symptoms were severe and the enema well retained 1 or even 2 extra drachms were given. Before administering the enema the skin round the anus was well smeared with vaseline and the catheter then passed up 3 to 6 inches. The ether mixture was passed into the funnel and allowed to flow into the rectum by its own weight. The rate of flow can be watched through the glass tube connecting the catheter to the tube. When all the enema has been run in, the catheter is rapidly withdrawn and usually none leaks out.

In many cases it did not begin to have any beneficial effect till after the second administration, and in severe cases actually aggravated the symptoms at first.

Elgood treated the first 25 cases with ether alone without drugs and the next 25 with ether and drugs; the latter improved so much more rapidly than those treated with ether alone that the remainder of the cases were always treated with both.

Belladonna was the most generally successful drug. In the cases summarized only four enemas or injections were given—in some cases one each day and in others on alternate days.

Of 58 cases treated by enemas 14 gave up the treatment owing to the parents' objections or because the child would not allow the administration of the enema. Of the remainder, 13 were failures and 31 successful. In addition to these 12 cases of pertussis were treated in the casualty department by enemas and five by injections. Nine were successful; the paroxysms were at once considerably diminished in number and violence, and ceased within a few days. Three

were failures. Two of these patients were already under treatment for bronchopneumonia and the third for anterior poliomyelitis.

SUMMARY.

1. Belladonna seems to be the most useful drug.
2. Ether will check the disease completely in 25 per cent. of cases.
3. Ether neither causes nor prevents complicating bronchitis; bronchitis already present is not a contra-indication to its use.
4. The method of administration seems to be of no importance provided the dose is large enough. Cases treated by intramuscular injections gave similar results.

The End-Results of Pleurisy with Effusion in Children.

By STAUTY GRAHAM, M.B., F.B.F.P.S.G.

Glasgow Medical Journal, July 1925.

THE modern conception of pleurisy with effusion is that it is of a tuberculous nature. This opinion is based not only upon the finding of the tubercle bacillus in the effusion and the lymphocytic nature of the exudate, but also on the fact that many of the patients subsequently develop pulmonary tuberculosis. Bowditch, for instance, traced 90 cases, and found that 32 of them (35.5 per cent.) subsequently became tuberculous. Of Hedges' 130 cases, 40 per cent. developed tuberculous lesions, while Cabot and Hammon in a large series respectively found subsequent tuberculosis in 52.9 per cent. and 29.7 per cent. of the cases.

It would seem from the few reports available that tuberculosis is a less frequent sequela of pleurisy in children than it is in adults.

The material used in the enquiry was obtained from the Royal Hospital for Sick Children, Glasgow. From 1914 to 1923 there were admitted to the wards of this hospital 56 cases of pleurisy with effusion. Only those cases in which the presence of the effusion had been demonstrated by aspiration were included. No death occurred in hospital, but not one on dismissal could be regarded as completely cured since dulness on percussion, with a deficient respiratory murmur, was still detectable at the affected base. As many of the cases as possible were traced and asked to report for x-ray and physical examination. The majority of the cases were seen from three to six years after the attack, and in no instance less than one year after dismissal from hospital.

The von Pirquet reaction was performed in 50 of these cases, and the results are summarised as follows:—

No. of cases tested,	..	50
" " giving negative reaction,	..	8
" " giving positive reaction,	..	42
" " reacting to bovine tuberculin alone,	..	16
" " reacting to human tuberculin alone	..	2
" " reacting to both human and bovine tuberculin,	..	24

Out of 39 cases which could be traced 7 developed a subsequent tuberculous lesion which has proved fatal in two cases, and is likely to prove fatal in a third. In all but one of these 7 cases, the subsequent tuberculosis had manifested itself within one year of the primary pleurisy. The single exception to this is a patient, who developed tuberculous peritonitis seven years after his attack of pleurisy. It therefore appears that the possibility of a recurrence of the tuberculosis in those children who have been well for one year after their attack of pleurisy, is slight.

The most common evidence of a previously existing pleurisy with effusion in a child is a flattening of the affected side. This was detected in 68 per cent. of the cases, but gives rise to no symptoms, and tends to disappear as adult life is reached.

It would seem unlikely that in pleurisy with effusion in children there is a primary lesion in the lung.

"The West Country Method of Rendering Milk Safe from Tubercle."

By H. SCURFIELD, M.D., D.P.H.,

Formerly Medical Officer of Health for Sheffield.

Medical Officer, July 25, 1925, p. 43.

It is curious that although most people like Devonshire cream, the making of it is as a rule confined to the western counties. Those who receive their milk in the raw state and wish to make it safe for children by a simple procedure may be interested to hear the details of the process. It is worth while for a household which consumes 3 or 4 pints a day. The 3 or 4 pints of milk are put in an enamelled iron pie-dish, allowed to stand for a few hours, then placed above the flame of a gas-ring turned very low, and slowly heated to 170°. It is advisable to raise the bottom of the pie-dish a little above the flame by some kind of iron ring or frame. As soon as the milk reaches 170°, it is taken off and put to stand in a cool larder. The cream is skimmed off the next morning and the residual "scald" milk is used for every other household purpose. The children of the house thus get their pint of milk in the form of Devonshire cream and scald milk. The amount of gas required to heat the milk is certainly not more than the gas required to bring milk to the boil.

The process is only available for households which receive their milk in the raw state.

For those who have not gas, any form of heat which answers the purpose will do equally well.

The ordinary method adopted in a Devonshire farmhouse is to heat the milk in earthenware glaze-lined puncheons, holding about 6 quarts each, on the hot plate of the closed range.

Some General Reflections on Public Health Administration.

By J. H. L. CUMPSTON, M.D. (Melb.), D.P.H. (Lond.).
Lancet, July 11, 1925, p. 83.

DR. CUMPSTON deals with distribution of legal responsibility between central and local authorities in various countries and concludes that all of these English-speaking countries, with English tradition as a foundation, have evolved towards an increasing local self-government; but the distribution of authority between the central authority and the local authority has taken different forms in different countries. In England there is the nearest approach to administrative regularity with wide powers of local autonomy and general powers of control and supervision by the central authority. But even in England the evolution of the public health system has produced anomalies—the distribution of health functions between the local authority and the county not being such as to satisfy many whose opinion is valuable. Moreover, the equipment and organisation of efficient public health administration to-day are beyond the resources of many of the 649 rural district councils, and the necessity for finding some more satisfactory system of organisation and for expressing such in the legal code is becoming increasingly apparent.

From these examples it is clear that whether health administration started from a centralised autocracy or from localised autonomy, all governmental systems are reaching, by different paths, a type of health administration more or less uniform. The routine local functions, principally control of the environment, are the concern of the local authority, however, large or small. The general direction of health policy, a paternal supervision, and the control of matters of common application are the duty of the central authority. It is in relation to the intermediate unit that confusion exists, and an analytical contemplation of the whole field impresses one with the conviction that difficulty mainly arises from the increasing range of matters of individual hygiene constantly being brought within the scope of official public health administration.

A recent survey of many practical attempts to codify this whole problem in legal expression as well as in administrative experiment has confirmed the opinion that a general review of the administrative public health system, at least in English-speaking countries, is overdue. The excessive attention recently paid to matters of individual hygiene, to "campaigns," "demonstrations," and the like, has obscured the necessity for progressive order and good government marching in step with other progress—and legal and administrative confusion is imminent where it has not already occurred. A definition of functions, possibly a modification of both the legal code and the administrative systems, is required, and particularly it is necessary that the diffusion of functions among many authorities shall cease and a logical system of graded responsibility be introduced.

The Commonwealth Government in Australia has just appointed a Royal Commission to suggest an organised scheme of rational progress, with defined responsibility distributed amongst the different grades of governmental units, and it is expected that great advances will result from the work of this Commission.

Cow's Milk in Infant Feeding.

British Medical Journal, May 9, 1925.

At a meeting, of the Section for the Study of Disease in Children, of the Royal Society of Medicine, on April 24th, Dr. Leonard Findlay opened a discussion of the question whether modification of cow's milk was necessary in infant feeding.

Dr. Findlay, referring to the generality of infants, had no hesitation in answering the question with a negative. He thought that raw milk ran so many risks of contamination that this danger should not be inflicted on children under 5 years, and pointed out that the ideal—a perfectly clean milk—was economically impossible of attainment. Boiled milk had the advantage of being more digestible than raw milk, and only lacked the antiscorbutic vitamin, which could easily be added. In pathological states, such as fat intolerance, some modification of cow's milk was necessary, but for the average infant Dr. Findlay maintained that whole cow's milk was the best substitute for breast milk. The difference in composition between human and cow's milk would seem at the first glance to warrant modification, and the chief discrepancy was that between the two protein figures. Protein was always dependent for its action upon its constituent amino-acids. The intra-molecular composition of the amino-acids of different proteins varied so greatly that an effective modification was impossible in the present state of our knowledge. Secondly, there was proof available that children were well able to digest whole milk; experiments on their metabolic balance had demonstrated this satisfactorily. There was, moreover, no evidence that a marasmic infant was less able to thrive on whole cow's milk than a normally nourished infant. Dr. Findlay had fed infants on diluted milk, peptonized milk, and citrated milk, but had always returned to the use of unmodified cow's milk. The vast majority of infants thrive on a diet of whole cow's milk. He therefore felt that the modification of cow's milk was uncalled for, except in certain pathological states, and possibly occasionally for infants under 3 weeks old.

Dr. Hugh Thursfield had found that children deprived of breast milk took unmodified boiled cow's milk, protected by an antiscorbutic, with enjoyment, and digested it well. Advice was most frequently asked for children already ailing from some cause or other; generally caused by disproportions in the feeding. It thus became a necessary part of the treatment to modify the food with regard to the particular constituent at fault in the previous diet. It was generally believed by the laity that there was some optimum food for infants which should be defined by the doctors. In his opinion there was doubtless such an optimum for

each individual infant, but the average best at present attainable was represented by boiled cow's milk for the generality of healthy infants.

Dr. R. C. Jewesbury believed that it was absolutely essential to modify cow's milk, taking the average constitution of breast milk as the standard. He considered that there was very little variation in the composition of breast milk if the breasts were completely emptied on each occasion. The method of percentage feeding on this basis, started by Sir Frederick Truby King in New Zealand, and used by himself and others in England, had given every success. Dr. Jewesbury showed charts of the weight curves of infants who were much below normal until they were fed on a percentage modification of cow's milk, when they immediately began to gain and rapidly reached the normal curve.

The Mission to Lepers (Indian Auxiliary).

THE following is an abstract from *The Statesman*, Calcutta, of the 10th December, 1925, on the present position of the Indian Auxiliary of the Mission to Lepers:—

For one-and-fifty years the Mission to Lepers (Indian Auxiliary) has been providing hospitality for some thousands of men and women and children who, but for the Mission's asylums, would look in vain for sympathetic care. "To see the happy faces of the inmates," wrote Mr. Gandhi after visiting the Purulia Leper Asylum last year, "was to realise what loving service rendered in the name of God can do."

The report of the Mission for 1924-25, records *inter alia* the opening of two new asylums—one near Dhaindari in the Central Provinces and the other at Vada-thorasalur in the Madras Presidency—and the introduction of the latest methods of treatment, but as the secretary to the Mission remarks it is of the unsatisfactory nature of a report that it cannot tell the things that really matter most. "It is the individual that matters far more than buildings and tables of statistics. And though a report can tell of buildings erected, record financial position, and tabulate numbers of patients, it can give but little idea of what the Mission Asylums and the Home for Healthy Children mean to each of the 5,000 inmates."

In December of last year Mr. Anderson, the General Secretary of the Mission, on a visit to India, presided at a conference at Naini, which discussed the future policy of the Mission as affected by improved medical treatment. It is hoped so to organise the various institutions that certain ones will be specially fitted for the treatment of early cases, while others will care more especially for the many advanced cases for whom provision must be made until death.

The report states that there has been an increasing eagerness shown to take advantage of the latest methods of treatment, and the desire of the Mission to Lepers to make it possible for its institutions to do the best medical work possible is indicated in the appointment of Dr. R. G. Cochrane to the new post of Secretary for Medical work. Dr. Cochrane came to India in the autumn of 1924 and has since been making a detailed study of the medical work at the various stations with a view to formulating a policy which will most effectively make the Mission to Lepers' Institutions a potent agency in the treatment of hopeful cases. Although the majority of cases in Mission Asylums are advanced ones, and are often suffering from the disabling effects of leprosy rather than from the active disease, yet the modern treatment brings its challenge to provide for every hopeful case the fullest opportunity of recovery. Dr. Cochrane's movements through India have also enabled him to give numerous lectures of an educational character.

In pursuance of the recommendations of the Naini Conference various members of Asylum staffs have in the last year taken a special course at the School of Tropical Medicine, Calcutta.

The work of the Mission is largely that of caring for lepers who are already suffering from the worst effects of the disease. Their need becomes no less because for the early case there is increased hope. The number of applications for admission to numerous asylums has increased, and with its heavy financial burdens, the Mission is faced with greater responsibilities with a smaller income. The income in India last year was Rs. 6,73,470; of this total Rs. 2,57,785 was received from Government and municipal grants-in-aid, the balance of Rs. 4,15,665 representing private subscriptions. Of this amount only Rs. 63,765 was received direct in India, the remainder coming from friends overseas.

The Treatment of Chronic Arthritis.

British Med. Jour., October 10, 1925, p. 633.

At the annual meeting of the British Medical Association "The Treatment of Chronic Arthritis" was discussed by Sir Thomas Horder. The etiological factors are various, and in the great majority of cases, if not in all, more than one factor is present. In such cases the more correctly the value of the particular factors is estimated, the better will be the response to treatment. In some cases there are etiological factors which are obscure.

The infective factor is present to some extent in almost all cases of chronic arthritis. Even in cases which at first sight seem independent of infection there are good reasons for thinking that the microbic factor is contributory. Joint disease due primarily to trauma, to gout, and to trophic diseases of the spinal cord are instances of this statement.

A table of the various types of arthritis arranged according as the element of infection is or is not a dominant etiological factor is given.

INFECTIVE FACTOR	Joint Disease.
	High.
↑	Gonorrhoeal rheumatism.
	Chronic pyæmia.
	Arthritis due to streptococcal, pneumococcal, dysenteric, and coliform infections.
	Tuberculous and syphilitic arthritis.
↓	Arthritis in association with focal sepsis.
	"Rheumatoid" arthritis.
	Osteo-arthritis.
↓	Gout.
	Arthritis in tabes, syringomyelia, hemiplegia, and paralysis agitans.
Low.	Trauma.

The brackets indicate groups of cases having close etiological resemblances.

Arthritis as an expression of focal sepsis forms an intermediate group between the cases of direct joint infection and those termed "rheumatoid" which, owing to our present ignorance of the degree to which the element of infection is present, form the crux of the therapeutic problem.

In this intermediate group, drainage or other appropriate treatment of the area of focal infection is the first step in treatment. If more than one area is involved it is important to determine as far as possible which is primary, and attend to that first. If teeth and tonsils, or teeth and gastro-intestinal tract, are both involved, the teeth should receive thorough attention and an interval be allowed before drastic measures are employed in regard to the tonsils and the bowel. So also with the throat or nose on the one hand and the rest of the respiratory tract on the other.

Streptococci, both hæmolytic and non-hæmolytic, are probably by far the most common micro-organisms concerned in the infective element in arthritis. This holds good equally for intestinal as for other subinfections.

Advantage may be taken of this fact in treatment when the bacteriological evidence is indecisive.

Antigen therapy should be supplementary to drainage of the infected area, not a substitute for it. The decision to employ antigens should be deliberate, and, the decision being made, the choice of remedy and system of dosage should be very carefully considered. The patient should be warned against expecting quick results and encouraged to co-operate in a thorough trial. His immunity mechanism should not be flogged, but rather coaxed, by the remedy.

In undertaking drainage of the intestine, consider the diet, both from the point of view of lowering the bacterial content and from that of mechanical cleansing. These considerations are probably of greater importance than is the use of "intestinal antiseptics." Amongst the latter measures, however, the older agents, such as mercury and salol, should not be forgotten. The value of a drug is rarely proportionate directly to the amount of money spent upon advertising it.

In the great majority of cases chronic arthritis is part of a general disease. The patient requires treatment as much as, and sometimes more than, the joints. This fact involves two important factors—the nutritional and the nervous; they overlap in many cases.

In treating the nutritional factor the general habits must be passed in review; much the same régime should be adopted as is followed in any case of chronic infection—for example, as in pulmonary tuberculosis; ample fresh air, bodily and mental relaxation, the avoidance of codding, a full and liberal dietary, and graduated exercise. Diet fads are to be rigidly avoided. The best drugs in this connexion are arsenic, iron, cod-liver oil, and the hypophosphites.

On the nervous plane a series of strains should be remembered: emotional shock, the prolonged nursing of friends or relatives, child-bearing, the menopause, fears of crippling, etc. Habits of invalidism and the paraphernalia of the sick-room must be combated. Small doses of thyroid are often helpful, especially in the older patients.

The metabolic factor is difficult to assess, but should be carefully sought. The experienced observer can often detect the factor of gout even in the presence of obvious sepsis. To omit appropriate treatment is to leave untouched an important and sometimes very amenable part of the pathogenesis. Colchicum and alkalies are indicated for acute or subacute exacerbations; in chronic conditions atophan or atouquinol should be tried. The last named drug is sometimes very useful even when gout is not obviously present.

For effusions iodine is invaluable. Nothing seems to excel the tincture, given in the form of the French Codex preparation (10 per cent.). It is best ordered in minim doses, taken in milk, between meals: 1 minim a day, with an increment of 1 minim daily until 30 minims are reached, keeping at this dose for a month, and then gradually diminishing, the course being thus one of three months' duration. When the dose reaches 6 minims daily it may be taken in two doses, and when the dose reaches 9 minims it may be taken in three doses. For the relief of pain in addition to local measures there is nothing as a rule so helpful as aspirin. Climate is certainly less popular in treatment to-day than formerly. The indifferent food, the risk of intercurrent infections, and the strain of travelling make a trip to foreign climes of dubious advantage. There is the added obstacle that such an enterprise holds up most of the other helpful measures of treatment. There is a large function for spa treatments, quite apart from the local effects upon the joints. Of radium waters and radio-active mud we are only now beginning to learn the potentialities.

In the local treatment it is necessary to remember that structures other than the mere tissues of the joint proper show the effects of inflammation and malnutrition: the bursa, the tendon sheaths, the fasciae, the nerve trunks, the skin, and especially the muscles. If local

measures are to be really useful, all these must be passed in review and their condition noted. No mere rule of thumb treatment is of any service; rather does such absence of method or reason often render disservice. Massage, so eminently useful in the majority of cases, is grossly abused in others, where muscle spasm exists as a contraindication, though usually temporary. Ionization and diathermy have their advocates, and what is termed, with an attractive note of hope and economy, electrical massage. Unless the electrotherapist can tell us clearly what is his conception of the pathology of the local condition and what it is he aims at doing, we may at least hesitate to follow his advice, however enthusiastically given. There is one *sine qua non* in regard to all local measures, and that is the necessity for getting the patient's confidence; unless this is secured the result is doomed to failure.

In the restoration to function of the wasted muscles and the stiffened joint, active movements undertaken by the patient take a very prominent place. No amount of merely passive movement ever succeeds in substitution for this. The patient must be constantly encouraged into making these efforts for herself under pain of permanent crippling. Simple forms of apparatus which assist voluntary efforts are useful—balls of different sizes to be clenched by the hands, the wheel of a sewing machine for the wrists and shoulders, a treadle machine for the ankle and hip.

General Effects of Local Treatment.

All efforts made to restore and improve the function of diseased joints react beneficially on the disease itself. This should be explained to the patient. Moreover, the practitioner should have constantly before him the possibility of spontaneous arrest of the disease, or arrest, the result of his general treatment.

The orthopaedic treatment of fixed joints resulting from chronic arthritis is a science and practice in itself. Its importance is even yet scarcely appreciated. The first essential to correct methods is a good radiogram. The second is examination under a general anæsthetic. Experience shows that in many cases several slight forcible movements, at intervals determined by the particular case, are better than one severe wrench.

Dr. Preston King, Honorary Consulting Physician, Royal Mineral Water Hospital, Bath, dealt with spa treatment.

"Bath possesses the only thermal springs in the United Kingdom. The waters rise to the surface at a temperature of 117° F. and in a volume of about half a million gallons daily. The analysis of these waters is open to you all, and is contained in the handbooks that are published, so I need not trouble you with that now, beyond saying that, they contain no specially active salts, and are, therefore, classed among those that are called "indifferent." These various "indifferent" spa waters, however, are all-known to have a special character of their own in the treatment of disease, but to what that special character is due we do not know. Bath waters are slightly diuretic as compared with ordinary water, and are also radio-active to a marked degree. Naturally this latter fact is made much of by the city authorities in matters of advertisement; but whether we are justified in laying any stress on this property to explain their action I do not know. I do know this, however, and it is one thing that is certain about their use—and that is that certain cases, and especially those which are due to gout, do improve here in a wonderful way."

"There is one other factor which helps, and that is faith, which makes towards recovery. The patient, after a long illness and the use of many remedies, finds himself at a health resort, amid surroundings laid out for treatment, and in a place where the whole atmosphere breathes hopes of recovery."

In treating chronic arthritis by hydrotherapeutic methods we are treating results, and not causes, and the cases as we see them will vary as I have said, from those of slight stiffness and pain on movement and a little synovial thickening, to those later stages of disorganized

joints with eroded cartilage, irregular bone formation, and fibrous or even bony ankylosis. These patients come for cure; but it is obvious that no benefit, beyond perhaps some alleviation of pain, is possible.

In the treatment of chronic arthritis by waters, or by any other means, it is not only stiff and painful joints, but also the patient behind them, that we have to think of. It is of little use in the end to see the swellings reduced and the joints more free if the general health suffers in the process. This especially applies to those asthenic cases of rheumatoid arthritis in women where the fusiform synovial enlargement of the joints, especially of the smaller ones, is accompanied by a quick pulse, a moist skin, and general debility. Such cases not only do not improve but tend actually to get worse by bathing. For them a general tonic treatment, with good food, fresh air, and massage, is by far the best.

In treating chronic arthritis by means of baths, the hot water lessens the tension and relieves the pain and allows more movement to the joint. Bath, with its abundance of hot water, can supply this treatment freely in its so-called deep and reclining baths. This is its oldest form of cure, the one upon which its reputation was first founded, and it still remains its peculiar speciality. Immersion in the water is followed by the pack in hot sheets and blankets for from fifteen to twenty minutes, and this time might be extended with benefit and comfort. A glass of the water is taken while in the bath, and this encourages a more healthy action of the skin during the pack.

Whether this is exactly so or not, the fact remains that much benefit follows a thorough washing out of the colon. This is done by means of the Plombieres system, where a pint or more of hot water is allowed to flow into the rectum, acting as an ordinary enema, to be followed by another and more copious flow which reaches the whole course of the colon.

Many cases of chronic arthritis improve more when active movements on their own part are encouraged rather than when they are subject to the passive movements by the masseur. For these the warm swimming-bath is very useful.

The tone of the muscles is restored and there are no muscles so suitable for moving a joint towards recovery as are its own. Ionization can be applied directly to the joints affected, through packs of lint soaked in a weak solution of sodium salicylate, lithia, or an iodide; it is often of great use in reducing the synovial swelling. Then also there is the radiant heat, either by the Greville or the Dowsing steam, where the whole body or a particular joint is exposed to a temperature considerably above boiling point. And then there is a room which looks like a cross between a gymnasium and a torture chamber, where by mechanical contrivances passive or active movements can be obtained by means of wheels and pulleys. This system is useful in some of these cases of chronic arthritis where the stiffness of a joint is due to fibrous adhesions. It can easily be understood, however, that it needs using with care, lest by too much force the condition of some quiet joint be converted into a more acute and painful arthritis."

Reviews.

COLLECTED ADDRESSES AND LABORATORY STUDIES OF THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE. VOL. I; 1924-25.—Compiled by Professor R. T. Lelper, F.R.S.

THE London School of Tropical Medicine has now become the Division of Tropical Medicine and Hygiene of the new London School of Hygiene and Tropical Medicine; and with the change in status of the School it was felt desirable to slightly alter the form and scope of its "Collected Papers." In this form, as an annual volume, the work of the School will become better known and exchanges of literature will be facilitated.

The volume before us is a notable addition to the literature in tropical medicine in all its aspects. It consists of reprints of over 40 papers from 16 different journals, bound into a single volume. As these have all appeared in press before, and some of them have already been abstracted or reviewed in our columns, the book scarcely calls for review except as a collective publication. It will interest the many old students of the London School however to know of its existence. No price is given, and we suppose that the volume is one for private circulation only.

We have browsed through its very attractive pages with much appreciation. Dr. Andrew Balfour's addresses are fascinating reading. "New conceptions in the teaching of Public Health" is an outline of the inception and policy of the new London School of Hygiene and Tropical Medicine. "The Historical Aspects of Malaria" is a forceful and picturesque essay. "The Trend of Modern Hygiene" is an address which will appeal to all sanitarians; whilst "Vistas and Visions: Some Aspects of the Colonial Medical Services" is almost a world-wide review of the chief medical and hygienic problems of the British Empire.

The actual papers themselves naturally cover a very wide field, dealing with tropical diseases, bacteriology, protozoology, helminthology, entomology and even veterinary medicine. The whole volume is a fine and worthy publication of the famous School from which it is issued.

TAYLOR'S PRACTICE OF MEDICINE, 13TH EDITION.—By E. P. Poulton, M.D., F.R.C.P. London: J. & A. Churchill, 1925. Pp. 1063, with 48 plates and 93 text figs. Price, 28s. net.

TAYLOR'S "Medicine" has held its position as the leading or one of the leading text-books on medicine during the present generation. It is pleasing to find that the latest edition ensures a continuance of the place of honour which has so long been held by our old friend. Since the former edition was issued three years ago, Dr. Poulton has extensively revised the work, and it is now thoroughly abreast of the times. Several new articles have been added. A new feature has been introduced, numbered references are given to the most important articles in the recent literature of medicine, so that it will be easy for the reader to obtain more detailed information on matters which have been subjects of recent advances in our knowledge. The radiograms which are given are of great value to the student. The book is thoroughly up-to-date, but it is pleasing to note that there has been no frantic effort to include unproved "up to the minute" information. The articles on tropical diseases are less satisfactory than those on the common diseases of cooler countries, but this is a common feature of general text-books of medicine. Such closely related diseases as sandfly fever and dengue are widely separated from each other in the book. The treatment of cutaneous leishmaniasis is given at the end of the brief article on kala-azar but no account of the disease itself is given. Hunger oedema is stated to be "probably identical with epidemic dropsy," and generally speaking, we cannot recommend the volume as being specially helpful to the student of tropical medicine. The articles on the great diseases of colder climates are on quite a different plane, they are authoritative and in every way satisfying; if any are to be picked out for special praise they are those on rickets, asthma, pernicious anaemia and peptic ulcer.

The book will certainly be a great success; what is more important, it thoroughly deserves to be so.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY.—By W. A. Newman Dorland, A.M., M.D., F.A.C.S. Philadelphia & London: W. B. Saunders Co. 13th. Edition, 1925. Pp. 1344, profusely illustrated; flexible binding with thumb index. Price, 37s. 6d. net.

THIS splendid work is now a classic, and has been through thirteen editions since its first appearance in

1900. In the preface to the thirteenth edition, it is stated that some 2,500 new words have been added. The book is something more than a mere dictionary; it is a compend of the terms used in medicine, surgery, dentistry, pharmacy, chemistry, nursing, veterinary science, biology and even medical biography. A very valuable feature of the work is that the derivation of each word is given, together with much collateral information of an encyclopædic character.

The work is thus exhaustive and exceedingly valuable; its colour plates and numerous illustrations alone make it very attractive. To anyone with much writing for medical journals to do, it is a veritable necessity; to even the general practitioner, however, it will make a very strong appeal. In one respect the book is American rather than English; for instance, we looked up "ætiology"—which is the correct etymological spelling of the word, but found only "etiology," which may be more popular but is less correct. This however is an exceedingly minor point. We looked up several different tropical diseases and were pleased to find the information given accurate and up-to-date. From *z* to *z*ymurgy, the volume is replete with information. We wish that all of the more frequent of our contributors would purchase and use this celebrated dictionary; it would lighten our editorial duties by at least 50 per cent. As it is, we shall frequently be compelled to resort to it ourselves. Anyone who thinks that he can spell has only to try editorial work for a year or two; he will then find that correcting the spelling of others has ruined his own. The wider the circulation of this splendid work in India, the better we shall be pleased.

THE ART OF MEDICAL TREATMENT. WITH REFERENCE BOTH TO THE PATIENT AND TO HIS FRIENDS.—By Francis W. Palfrey, M.D., Visiting Physician, Boston City Hospital, Instructor in Medicine, Harvard University. London and Philadelphia: W. B. Saunders, Ltd. Pp. 463. Price, Cloth 21s. net.

This book aims at giving the essentials of medical treatment in an explicit and condensed form. The instructions are on the same lines as those contained in the standard text-books of medicine, and for this reason the average medical student is not likely to find this separate volume an essential in the acquisition of knowledge.

The practitioner who desires to bring his knowledge up-to-date will find the volume useful and instructive. As is usual in such books the sections on tropical diseases are neither so full nor so up-to-date as could be desired. Most of us would appreciate the inclusion of a few prescriptions; though the writing of a prescription forms only one part of the treatment of a patient it is nevertheless an important part.

The book is produced in the usual excellent style of Messrs. Saunders.

SYNOPSIS OF MEDICINE.—By H. Letheby Tidy, M.D. 4th Edition. Bristol: John Wright & Sons, Ltd., 1925. Pp. 1000. Price, 21s. net.

A HANDY book containing all important recent information useful for students in revision, for practitioners in looking up the modern literature and for teachers before lecturing. This edition is entirely rewritten and the recent work on asthma, diabetes and jaundice is included. Students of tropical medicine will be disappointed in not finding in it sufficient up-to-date information. The author, however, is to be congratulated as the book is an excellent general synopsis of general medicine.

CATECHISM SERIES. EDINBURGH: E. & S. LIVINGSTONE. MIDWIFERY; PARTS I & II. MEDICAL BACTERIOLOGY AND PROTOZOOLOGY.—By W. R. Logan, M.D., F.R.C.P.E.; Parts I & II. **DISEASES OF THE EYE.** By W. G. Sym, M.D., F.R.C.S.E. Price, 1s. 6d. net each part.

We confess that we do not like this type of book. Medicine is a science and art which has to be mastered, and spoon-feeding of students, a bad habit in the

English medical schools, is even more dangerous in India. Yet there is no doubt that this little class of book is very popular, and the volumes which we have received are all in their second or third edition. They meet the need of the medical student for final rapid revision for examinations, although they can in no way replace systematic text-books. The "Catechism Series" is well got up, well printed and handy. What is more, the information given is accurate, and the publishers are a very well known firm with a high reputation. The price is within reach of the pocket of even the poorest student.

THE MEDICAL ANNUAL GENERAL INDEX, 1915—1924.—Published by John Wright & Sons, Ltd., Bristol. Pp. 301. Price, 12s. 6d. net.

This index deals with the contents of the last ten volumes of the *Medical Annual*. It will be found invaluable to the thousands of medical men who subscribe to the *Annual*, constituting as it does a guide, to all the most important literature of the past ten years.

THE STUDENTS' POCKET PRESCRIBER.—By Dr. D. M. Macdonald, M.D., F.R.C.P.E. 9th Edition. Edinburgh; E. & D. Livingstone, 1925. Pp. 226. Price, 3s. net.

In a miniature volume which will readily go into the vest pocket, the author has condensed no less than 551 prescriptions with directions for use. They are arranged according to the diseases for which they are intended.

There is a great deal of information on prescribing, a table of doses, a vocabulary, diet tables, etc. This handy and cheap volume will be found very useful by students and doctors. It has reached the 9th edition and is becoming increasingly popular.

THE BOOK OF PRESCRIPTIONS.—By E. W. Lucas, C.B.E., and H. B. Stevens, O.B.E. 11th Edition. London: J. & A. Churchill, 1926. Pp. 382. Price, 10s. 6d.

THE 11th edition of this useful and well known handbook has been issued after nearly 12 years. The present edition has been thoroughly revised and a large number of useless remedies have been deleted, while new useful remedies such as new compounds of arsenic have been introduced. Brief notes on the pharmacological action of drugs enhance the value of the book and we recommend it to the notice of students and practitioners.

FAVOURITE PRESCRIPTIONS.—By Esplne Ward, M.D. (Belfast). London: J. & A. Churchill, 1926. Pp. 96. Price, 5s. net.

This book is divided into three parts. The first part consists of dosage tables, the second part gives hints for treatment of poisoning, and the third part gives favourite prescriptions arranged according to the diseases and symptoms for which they are used. The prescriptions given are well selected, all incompatibilities being carefully avoided. The book is interleaved, thus providing room for any additions. We feel certain this little edition will be of use to students going in for examination, and to practitioners generally.

ELEMENTS OF SURFACE ANATOMY.—By I. McLaren Thompson, B.Sc., M.B., Ch.B. (Edn.), Assistant Professor of Anatomy, McGill University, Montreal. Edinburgh: E. & S. Livingstone, 1925. Pp. 172. Available from Messrs. Butterworth & Co. (India), Ltd., Post Box 251, Calcutta. Price, Rs. 4-2 or 5s. 6d.

This small book consists of five chapters dealing with the surface anatomy of the five parts of the human body, viz., the head, the neck, the trunk, the superior extremity and the inferior extremity. The English translation of the B. N. A. has been adopted in the description, but the old nomenclature has with advantage been inserted within parentheses, the first time each term occurs. By including the clinical

significance of the surface anatomy of the parts the author has broken the dull monotony of points and lines and made the subject interesting. Attempts have been made to point out the correlation of the facts of the surface anatomy to those of descriptive anatomy and students of medicine will appreciate them very much. It is true that surface anatomy can only be learnt by marking the position of the parts on the living body, but the illustrations added to this book will help in that direction and make the book more useful and attractive to students in general. The descriptions have been written in a very simple, clear and lucid style. The system of tabulation adopted in some places will be very useful to students.

We strongly recommend the book to every student of medicine, who will find it interesting and useful reading.

HAND ATLAS OF HUMAN ANATOMY.—By Werner Spalteholz, Professor of Anatomy, Leipzig. Translated by L. F. Barker, Professor of Clinical Medicine, Johns Hopkins University. 5th Edition in English. London: J. B. Lippincott, 1925. Three Vols., Price £4-0-0 net per set. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Calcutta. Price, Rs. 60 net per set.

This beautiful atlas has been translated into English, Italian, Russian and Spanish. In three volumes there are nearly a thousand excellent illustrations, many of them in colours.

The atlas will be much appreciated by surgeons and anatomists, also by medical men who desire to refresh their knowledge of anatomy in the easiest possible manner.

In common with almost all works on anatomy the book ignores the blood supply of the spinal cord. The lymphatic system also is omitted. The atlas would be greatly improved by a set of illustrations showing the bones and viscera as seen by radiography.

Apart from these omissions there can be nothing but praise for the beautiful and accurate plates which are produced in the best German style. The text is concise and to the point, and though the older generation of medical men are more familiar with the old English nomenclature they will have no difficulty in recognizing the international Latin names which are employed.

MANIPULATIVE SURGERY: PRINCIPLES AND PRACTICE.—By A. G. Timbrell Fisher, M.C., F.R.C.S. London: H. K. Lewis & Co. Pp. VIII plus 168. Illustrations, 62. Price 7s. 6d. net.

This book will be welcomed by those who are forced to admit the successes of the bone-setters and who desire to read an authoritative account of manipulative methods by a skilled surgeon.

The author deplores the obstinately conservative attitude of the medical profession towards manipulation and in this connection records with approval the reply of John Hunter to Sir Astley Cooper who reminded him that a year before, he had expressed a different opinion. Hunter's reply was "Very likely I did, I hope I grow wiser every year." The slow and painful rise of surgery is described, how in 1745 the surgeons of London were set free from their association with the old company, the "Masters of the Mystery and Commonalty of the Barbers and Surgeons of London" and how early in the nineteenth century the Royal College of Surgeons was founded. Hunter advocated movement of inflamed joints after the subsidence of acute symptoms, but a new school of thought was introduced by Hilton and Thomas who believed that rest could not be overdone. These surgeons were probably influenced by the havoc which was wrought by the reckless bone-setters of the early nineteenth century. Sir James Paget in 1867 enumerated "Cases that Bone-setters Cure" and advocated learning what was good from the bone-setters.

Wharton Hood, Sir Robert Jones, and others have advocated a liberal attitude towards manipulation, but even now the old prejudices are but slowly dying and

there is still much room for improvement in the teaching of manipulative methods. The chief difficulty in connection with manipulation is to decide on the cases which are suitable and on the time when manipulation should be undertaken and it is on these points that the book under review is most helpful. There will always be cases in which the cautious surgeon holds his hand and which are relieved by the more daring and less instructed bone-setter, but on the other hand patients will gradually learn that considerable risk attends treatment by persons who are not conversant with the pitfalls of the surgery of joints. The future development of manipulative surgery will probably be in the direction of specialism and it is essential that the medical profession should foster the formation of a class of surgeons who have a good knowledge of general surgical work and who have also received a special course of training in manipulative surgery. A refusal to admit that there is any virtue in manipulative technique will only result in forcing patients into the hands of the unqualified bone-setters to the detriment of the profession and the public. Mr. Fisher's book should be studied by every one who is engaged in surgical practice.

MALIGNANT DISEASE OF THE TESTICLE.—By Harold R. Dew, M.B., B.S. (Melbourne), F.R.C.S. (Eng.), F.A.C.S. London: H. K. Lewis & Co., Ltd., 1925. Pp. 168, with 52 illustrations including 5 coloured plates. Price, 21s. net.

This excellent monograph—unique of its kind—embodies the author's experience of malignant disease of the testicle, a subject that of recent years has increasingly interested pathologists and surgeons. It comprises a review of the literature and a study of 40 cases of this disease.

The author discusses the anatomy and development of the normal testis, the morbid anatomy, histology of testicular neoplasms, the frequency of the various types of tumours, the clinical aspects and diagnosis, the prognosis and treatment. The monograph is written in a clear and attractive style, is illustrated mostly from original specimens and includes an appendix of the case histories.

We congratulate the author on his work and strongly recommend it as of great value to surgeons who are interested in these diseases.

SOME ENCOURAGEMENTS IN CANCER SURGERY.—By G. Grey Turner, F.R.C.S. (Eng.). Bristol: John Wright & Sons, Ltd., 1925. Pp. 75. Price, 7s. 6d. net.

The surgery of malignant disease is full of disappointments; it is a record of much labour with too little reward. As a result there is a natural pessimism in the teaching and practice of this branch of surgery.

In this little book Mr. Grey Turner gives us a record of cases, early and late, where the disease has been eradicated for years, and we welcome the 'encouragements' which his industry has provided.

There are forty good illustrations and the book is admirably produced.

Earlier diagnosis is only possible when the public is better educated and the medical profession has a great responsibility in this direction.

Every surgeon will read Mr. Grey Turner's book with pleasure and profit. It is only by such collections of verified cases that we can properly realise how many lives can be saved and even seemingly hopeless cases added to our list of triumphs.

MODERN SURGERY: GENERAL AND OPERATIVE.—By John Chalmers DaCosta, M.D., LL.D., F.A.C.S. 9th Edition. Philadelphia & London: W. B. Saunders, Ltd., 1925. Pp. 1527, with 1200 illustrations. Price, 45s. net.

This well known work has run into its 9th edition and this in itself is its best commendation. The work is well illustrated, the print however is on the small side.

It is really an exhaustive work, and each section has been rewritten by someone specialised in that section. The references are numerous.

One notices with satisfaction, in such a subject as burns, that the old classification of first, second and third degrees is done away with and a proper classification substituted which deals only with the layers involved.

The writer has left out surgical bacteriology, asepsis and antisepsis in order to make room for other material. One is inclined to regard the omission of this groundwork of surgery as an error; asepsis is of much paramount importance in surgery. On the other hand the author has found space for an extensive consideration of carbon monoxide poisoning, asphyxia and drowning. Most surgeons would probably prefer to see an exhaustive account of asepsis, rather than of carbon monoxide poisoning. Electrothermic methods of treatment of neoplasms, and radium treatment rightly find a place.

The title "Modern Surgery" is well chosen and one can confidently recommend the work.

THE SURGERY OF PULMONARY TUBERCULOSIS.—By John Alexander, B.S., M.A., M.D. Published by Lea & Febiger, Philadelphia & New York, 1925. Pp. 356. Illustrated with 53 engravings and 12 plates.

THIS book goes thoroughly into the question of compression in the treatment of tuberculosis of the lungs.

The following paragraph explains the benefits to be hoped for from compression:—

"Pulmonary compression constitutes a 'physiologic amputation.' Stagnant secretions and products of degeneration are removed from the body and tend to cease to form because of pulmonary rest, subsidence of non-specific inflammation and encapsulation of the tuberculous lesions. After the modern Brauer or Wilms-Sauerbruch thoracoplasty there is little or no chest wall and mediastinal flutter and respiratory function of the compressed lung is greatly reduced and sometimes practically abolished. There occur a passive congestion in the blood-vessels and a stasis of lymph. The most striking anatomical result of pulmonary compression is a profuse proliferation of fibrous tissue which encapsulates the tuberculous lesions and closes cavities and renders the disease inactive."

There are two methods of producing compression, viz., by causing pneumothorax by introducing gas into the pleural cavity, and by the operation of thoracoplasty, which causes collapse of the one side of the chest by resection of the posterior portions of the ribs.

The comparative merits and demerits, dangers and uses of these two methods of producing compression are dealt with in chapter 5 and the following conclusion is arrived at:—

"In the future when the surgery of tuberculosis is more widely known and better understood it is likely that large numbers of far-advanced cases that are now treated with pneumothorax will be operated upon by choice. At present, however, few physicians or surgeons would be so rash as to advise thoracoplasty as the first step in compression therapy, if they had reason to believe that an entirely satisfactory pneumothorax could be produced. Whether or not such a one is possible can be determined only by actual trial. If after a pneumothorax is obtained and a phrenicotomy added, it is found at any time and for any reason that continuation of the pneumothorax is liable to prove dangerous or unproductive of a satisfactory clinical result, thoracoplasty should promptly be performed. The preliminary pneumothorax and phrenicotomy and the improvement in the patient's condition, though it may only be slight, will have bettered the chances of the operation's success."

The two best known operations are thoroughly described, viz., "Wilms-Sauerbruch" and "Brauer." The latter differs from the former chiefly in removing a greater length of the ribs. The former operation

may be done either at one sitting or in two or even three stages. Some are in favour of resection of the first eleven ribs; when possible the author is in favour of resection of the first seven ribs along with phrenicotomy, which latter operation gives rest to the lower part of the lung by causing paralysis of that side of the diaphragm.

The operations and the results of operations are very well illustrated and the results of paravertebral thoracoplasty are given in tabular form.

In the early chapters the anatomy and physiology of the chest are dealt with very fully and clearly.

The book finishes with a very full bibliography of some 500 books and other writings.

This work should be in the hands of every surgeon and of every specialist in tuberculosis.

SWANZY'S HANDBOOK OF THE DISEASES OF THE EYE AND THEIR TREATMENT.—Edited by Louis Werner, M.B., F.R.C.S.I. 13th Edition. London: H. K. Lewis & Co., Ltd., 1925. Pp. xvi plus 698. Price, 21s. net.

THIS well known old text-book presents little change from previous editions; it has increased slightly in size and the chapters on diseases of the iris, ciliary body and choroid are partially rewritten. It remains as before a sound practical text-book embodying the experience of two very careful ophthalmologists, but does not describe the most modern methods of examination of treatment.

A TEXT-BOOK OF PHYSIOLOGY.—By William D. Zoethout, Ph.D. 2nd Edition. St. Louis: The C. V. Mosby Co., 1925. Pp. 616. Price, \$4.50.

THE author in the preface says that this book is intended to fill the gap between the larger text-books on the subject and those offering a briefer course. In this he has succeeded. The subject matter is discussed in a systematic manner and all the unnecessary detail has been left out. The sections dealing with the practical sides of nutrition, physical exercise, fatigue, etc., are particularly well written.

We recommend the book to students preparing for the examinations of the State Medical Faculty in this country.

THE HISTOLOGY OF THE MORE IMPORTANT HUMAN ENDOCRINE ORGANS AT VARIOUS AGES.—By Eugenia R. A. Cooper, M.D. London: Humphrey Milford, Oxford University Press, 1925. Pp. 119. Price 12s. 6d. net.

THIS publication represents a careful and detailed histological study of the pituitary, suprarenal, thyroid, parathyroid and thymus glands. The materials were obtained at various periods from intra-uterine existence to old age, and a useful description of their appearances is given as seen at different stages of development. Each description is terminated by a synopsis correlating structure with function.

The work will be found of much value by pathologists as a supplement to books dealing with general normal histology.

There are numerous illustrations which include many good photographs of gross and microscopical preparations.

INFECTION, IMMUNITY AND INFLAMMATION.—By F. B. Gurd, B.A., M.D., C.M., F.R.C.S. St. Louis: C. V. Mosby Co., 1924. Pp. 329. Price, \$5.00.

THE immediate object of this work is to present in a form suitable for clinicians the salient facts regarding hypersensitiveness and its relation to other immunological processes, for the purpose of controlling disease processes in man by serological methods. To this end the author has written a quite well arranged book. After a general presentation on the usual lines of the chief facts and theories of immunity, the latter

part of the book is devoted to the application of immunological principles to the control of disease in man. The contributions of immunology to practical therapeutics have, however, up to the present not been as extensive as was at one time expected, and this part of the field is therefore somewhat restricted.

A useful chapter on anaphylaxis in man is given. Vaccine and serum treatments are described in many diseases, e.g., pneumonia, diphtheria, tetanus, rabies, hay fever, etc., as also are the chief tests, the Schick and Dick reactions, etc.

Although the book is more especially concerned with hypersensitiveness, we think a chapter on the clinical interpretation of Wassermann results would have been worth including as the book is intended more particularly for clinicians; and the Wassermann test is perhaps the most striking contribution immunology has made to medicine. The only account given of this test is a brief description of the method and its underlying principles. There is a great deal of useful information given in the book which will no doubt be acceptable to clinicians for whom it is more particularly intended.

ESSENTIALS OF PSYCHIATRY.—By G. W. Henry, M.D. London: Balliere, Tindall & Cox, 1925. Pp. xiv plus 199. Price, 13s. 9d. net.

ALTHOUGH this book is in many respects a hotchpotch, there is a good deal in it which will repay careful study. As is only too common in American books, the language in which it is written makes it terribly tedious in places. To take one example, the short dedicatory note to Dr. William Logie Russell, is devoid of either grammar or sense.

Very few psychiatrists will agree with the author's views on the development of personality. For instance, it is hard to imagine any truth in the statement that the sexual instinct "is responsible for the formation of what has been called the social or herd instinct," especially, when on the next page the author observes, "during the period of adolescence there is frequently conflict between the sexual and social instincts." The very difficult question of a classification of mental disorders is discussed and there is much to be said in favour of the classification advocated by the author. There is a good chapter on psychiatric nursing by a former Directress of Nursing at the Bloomingdale Hospital. It is astonishing, but none the less gratifying, to learn that in certain hospitals in the United States 75 per cent. of the patients are admitted upon their own application.

Dr. Henry gives an interesting list of great men whose lives have shewn them to have been markedly psychopathic. It is curious that an American writer should have omitted Edgar Allan Poe from a list of this description.

The chapter devoted to the medico-legal aspects of psychiatry is very disappointing. Foreign readers would have liked more information on this very important subject to enable them to compare the attitude adopted towards insanity by American law with that adopted by the law of their own lands.

The book ends with a short note on the actual making of the book, in which is given a nominal roll of all the persons who took part in the work. There is also a very useful bibliography of works of reference published in English.

OBJECTIVE PSYCHOPATHOLOGY.—By G. V. Hamilton, M.D. St. Louis: C. V. Mosby Co., 1925. Pp. 354. Price, \$5.00.

THIS book is introduced to the public in a most enthusiastic preface by Professor Robert Yerkes, the eminent American psychologist. Professor Yerkes writes:—"Though little known and less understood by psychologists and psychopathologists, Hamilton's discoveries are undoubtedly of fundamental and far-

reaching importance. I venture to predict that he will presently find himself the leader of a school of psychopathology which will as importantly modify our current conceptions of reaction tendencies and their relations as has psycho-analytic methods our notions about mental content." Certainly Dr. Hamilton has written a very interesting book and that too in such a way as to place beyond question the honesty of his convictions. The author's researches have included not only nervous patients but relatively "normal" adults and children, as well as animals. Dr. Hamilton begins the exposition of his theory of the existence of what he terms a "persistent, non-adjustive, affective reaction" by discussing clinical reports on two hundred nervous cases.

The author pays tribute to the concepts of the psycho-analytical school of psychologists to whom, he states, he is indebted for help in formulating his views on the reactions of man and animals to sexual stimuli.

It is a matter for great regret that a mind which thinks so keenly as that of Dr. Hamilton's cannot express its thoughts in clearer language. Sympathetic readers of this book—of which there are sure to be many—cannot escape feelings of blank despair in their attempts to get hold of the exact meaning of a great deal they will encounter. To take only one example:—"Somatic discomforts and disabilities, and dysteleologic overt adjustive movements which are obviously not due to toxic, traumatic and other gross interferences with vegetative and behaviouristic functions, and which cannot be explained as direct reactions to any kind of discoverable stimulation, ought always to lead the clinician to a quest of stimulation to which the patient is more or less continuously subjected, to which he cannot acquire actual unresponsiveness and to which he cannot react directly without suffering a real or imagined disadvantage."

The book contains an admirable bibliography as well as a glossary of technical terms. The latter will be of much use to lay readers. There is a notable misprint on p. 223 where the name of the famous biological-psychologist, Lloyd Morgan, is spelt Lord Morgan!

Annual Reports.

ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH AND OF THE SANITARY ENGINEER, MADRAS, FOR THE YEAR 1924. MADRAS: SUPDT., GOVT. PRINTING 1925. PRICE RE 1-4-0.

MAJOR A. J. H. RUSSELL, M.D., D.P.H., I.M.S., continues in this report his most interesting series of annual reports, dealing with many important problems of public health, not peculiar to Madras, but of general interest in India. Thus he notes that the registration of vital statistics is as bad as ever; in 23 districts a total of 63,783 unregistered births was discovered. A proposal was made that the work of registration in union areas should be transferred to the Union Boards, but was not accepted by them. Official orders have now been issued that the compilation work of vital statistics shall in future be carried out in the Collector's office under supervision of the District Health Officer, whilst the simplification of the district monthly returns is under consideration and amendment of the Village Officers' Manual.

The birth rate of the Presidency shewed a definite rise, from 33.1 in 1923 to 34.9 in 1924; but the death rate also rose, from 22.2 to 24.5, and infantile mortality shewed 179.2 deaths per mille of registered births.

The district health staff, organised in 1923, continued to work during 1924. The most noticeable features of

the year were the large increase in cholera mortality and the considerable decrease in the mortality from plague. The cholera mortality, 51,971 deaths, was the highest recorded since 1918; the plague mortality, 3,922 deaths, one of the lowest figures ever recorded in Madras.

Cholera.—All districts in the Presidency except five were infected during the year, and the total death rate from cholera rose to 1.3 as against an average figure of 0.9 for the previous quinquennial average. Drought, famine and unfavourable climatic conditions favoured the spread of the disease, also the absence of protected water-supplies in many municipalities. Floods in several other districts also contributed to an increase of cholera. Thus the breaching of the banks of the Cauvery river damaged the water-supply of Trichinopoly town and was immediately followed by a severe outbreak of cholera with 1,507 deaths. Major Russell comments on the relative ease with which a single outbreak, notified early, can be dealt with; conditions are far otherwise when the disease suddenly becomes epidemic simultaneously in several different areas. A feature of the year was the increased willingness of the populace concerned to help in preventive measures; in one district over 5,000 contacts were inoculated with anti-cholera vaccine, only 4 of whom died,—all probably infected prior to inoculation. In order to improve and standardise preventive measures amended instructions have been issued and Horrock's box for chlorination of water-supplies has been supplied to a large number of local bodies.

A careful study of cholera incidence in the Presidency for the past 30 years shews that there is a definite six-yearly cycle, which holds good for every district in the Presidency. At least it may be claimed that the new district health staff have now a thorough knowledge of the main foci of infection and the routes of spread of the disease, and that such knowledge will be the basis for better devised and more efficient preventive measures.

Small-pox.—The history of the year bears out the contention of every Director of Public Health in India as to the vital need for more active measures. The death rate from the disease was 0.4 as against a quinquennial average of 0.5 per mille, but nearly two-thirds of the deaths occurred in seven districts. Here preventive measures were obviously lax. Over 75 per cent. of the mortality occurred among children under ten years of age, and 40 per cent. in children under one year; thus indicating the extent to which the child population is still unprotected. The disease tends to recur in Madras in 6 to 9 year cycles and the mortality usually reaches its maximum in March.

Plague shewed a notable decline, a death rate of 0.1 per mille as against a quinquennial average of 0.3. Salem, Coimbatore and Madura constitute the danger foci, whilst Hyderabad was virulently infected during the latter half of the year. A general review of the plague centres in the Presidency would seem to indicate that, if efficient preventive measures were taken in the towns, the control of plague would be very much simplified. Infection ordinarily commences in the market and grain-store areas, and if anti-plague funds were devoted to improvements in these places, the main sources of plague would be removed. Rat-trapping and poisoning are carried out only half-heartedly. "There is only one way to eliminate the rat; it must be built out of existence. The rat-proofing of new structures is relatively inexpensive, but the cost of rat-proofing old buildings is very considerable."

Fever.—The total mortality was 7.9 per mille, with a total of 322,356 deaths. The Nilgiris, contrary to all previous experience, shewed an abnormally high death rate, no less than 20.6 per mille; this was due to epidemic relapsing fever. Thanks to a vigorous campaign carried out by the Ootacamund Municipal Council and the Nilgiri District Board the epidemic was stamped out. The position with regard to malaria is being gradually cleared up; the anti-malarial unit attached to

the King Institute, Guindy, spent the year in carrying out surveys, whilst as a result of their activities and of those of the new district health staff accurate information is being collected. Funds however are very low, and it is most unfortunate that the second anti-malarial unit was disbanded as a measure of supposed "retrenchment"; the work of this unit had already probably saved government some twenty times its small cost of running. In some of the severely infected endemic areas a policy of free distribution of quinine wholesale seems to be the only policy possible, until the conditions present have been more fully investigated, and until funds for better directed measures are available.

A great contraction took place during the year in the area known to be infected with relapsing fever. Generally speaking, with the exception of the outbreak in the Nilgiris, the outbreaks were confined to small areas and were quickly stamped out. The experience with regard to this disease appears to bear out the statement in medical literature that epidemics usually die out after two years.

The incidence of dysentery and diarrhoea shewed a rise,—probably associated with the cholera epidemic, but the information at present available is not accurate enough for inferences to be drawn. Respiratory diseases gave a total mortality rate of 1.6 per mille, and probably much tuberculosis is concealed within this figure. Again the information is not accurate enough.

Hookworm disease.—The ankylostomiasis campaign was vigorously pushed during the year. The infection is ubiquitous throughout the Presidency; infection rates determined ranging from 55 to 90 per cent. No less than 123,100 treatments were administered, over 4,500 lectures given and much propaganda work carried out. The Rockefeller Foundation continued its work in this connection throughout the year.

Propaganda.—The need for the extension of maternity relief is shewn by the fact that it is estimated that in only some 43 per mille of cases of childbirth was skilled medical attendance available. The National Health and Baby Week was very successful. During the year 33,846 lectures were delivered at 27,346 centres, and during the special week an intensive campaign was carried out throughout the Presidency with the aid of lectures, leaflets, posters, lantern demonstrations and health exhibitions. The success of this branch of public health work is in no small measure due to the co-operation of such voluntary agencies as the Madras Health Council, the Rockefeller Foundation and the Red Cross Society. An annual grant of Rs. 8,000 for propaganda purposes has been given to the first named of these bodies.

Fairs and festivals.—Prior to the inauguration of the new district health scheme in April 1923, the arrangements made by local bodies to deal with the sanitation of fairs and festivals were totally inadequate. The value of the work of the district health staff in 1924 is shewn by the statement that "although practically every district in the Presidency was affected with cholera during the year, the great majority of festivals passed off without untoward incident." During the last two years conferences have been held in most districts concerned, attended by representatives of the local bodies, temple and railway authorities and departments concerned. The sources of income to local bodies from such fairs and festivals is not inconsiderable, and such income should be freely expended in public health measures.

Administration.—The reorganisation of the duties of the Assistant Directors of Public Health has tended to increase their usefulness and efficiency and to reduce the expenditure involved in administration to a minimum. In order to extend the health scheme to municipal areas, government provincialised the service of municipal health officers and included 11 posts of municipal health officers in the provincial cadre.

"The Government have read with interest Major Russell's full and illuminating report" runs the covering Government resolution, "and congratulate Dr. K. T.

Matthew, who acted as Director of Public Health during Major Russell's absence on leave during the year and the Assistant Directors of Public Health on the successful administration of the department."

REPORT ON VACCINATION IN THE MADRAS PRESIDENCY FOR THE YEAR 1924-25. BY MAJOR A. J. H. RUSSELL, M.D., D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, MADRAS, 1925: MADRAS: SUPERINTENDENT, GOVT. PRINTING. PRICE 8 ANNAS.

THE progress of vaccination in the Madras Presidency is indicated in this report by the facts that (a) the total number of operations exceeded two millions, an increase of 121,432 over the previous year; (b) the total number of successful cases reached a percentage of 83.7 as compared with 81.7 in the previous year and 69.6 in 1920-21; (c) successful infantile vaccinations increased in number by 79,327; (d) the cost per successful case worked out at 5 annas 9 pies as against 8 annas 9 pies in 1923-24; whilst (e) the total number of deaths from small-pox, 20,227 was 2,000 less than in the previous year.

During the three to four hottest months of the year vaccination was again suspended throughout the Presidency except in the Nilgiri district and Kodaikanal municipality; the period of suspension being utilized for the detection of unregistered births and of unprotected children. In one district, Tanjore, nearly 19,000 unprotected children were detected during the year, a fact very creditable to the district health staff, but very discreditable to the registrars responsible. Yet, despite the obvious fact that the services of vaccinators can be most usefully employed on this task during the hot weather off-season months, many local bodies either grant leave to vaccinators during this season, or dispense with their services, or utilise them for other work not bearing on vaccination.

In general Major Russell attributes to the following causes the retardation of vaccination in the province:—(a) the failure to introduce compulsory vaccination, especially in rural areas; (b) the reluctance of local bodies to enforce the provisions of law relating to compulsion; (c) the failure of local revenue officers to report promptly cases of small-pox and to correctly maintain the registers of vital statistics; (d) the failure on the part of many local bodies to employ an adequate and duly qualified staff of vaccinators; (e) the absence, especially in municipalities, of adequate supervision over the work of vaccinators; and (f) the activities, though limited at present, of the anti-vaccinationists.

Of the districts, 17 shewed an increase in the number of operations performed, and 8 a decrease. In municipalities there was an increase of 53,463 operations, Madras shewing an increase of 40,361. It is to be noted that, whereas a decrease in the number of operations is an obvious sign of slackness, the fact that there has been an increase is not always a sign of real improvement; in many cases such an increase may be due to actual or threatened outbreaks of small-pox. The maximum rate of successful cases per mille of population in municipalities was 153 at Ongole, the minimum 20.2 in Tiruvalur. The percentage of success was highest in municipal areas, 97.5, against 94.3 in local fund areas, and 91.8 in the (Government) Agency tracts. The lower percentages in the last two areas are due partly to the deterioration of the lymph in transit, and partly to delay in its use.

The Nandyal Taluk Board in Kurnool district is singled out as a good example of how *not* to do things; the district health officer reports that, despite the prevalence of small-pox in this locality, the Board has refused to declare vaccination compulsory, has refused to increase its permanent vaccination staff—which now consists of one vaccinator only, whilst it has also declined even to employ additional temporary staff.

As with public health in general, so with regard to vaccination, the introduction in 1923 of the district health board scheme has greatly improved matters. For

the first time on record the total number of vaccinations passed the figure of two millions, whilst the success rate for primary vaccinations reached the high figure of 94.6 per cent. The progress is bound to continue, although vaccination is still very backward in certain areas.

Capt. N. R. Ubhaya held the office of Assistant Director of Public Health (Vaccination) until July, when he proceeded on study leave. From that date Dr. P. Adiseshan, D.P.H. (Cantab.), was in charge. The improvement noted during the year is largely due to the energy and ability of both these officials.

ANNUAL PUBLIC HEALTH REPORT FOR THE YEAR 1924. CENTRAL PROVINCES AND BERAR. BY LIEUT.-COLONEL H. G. STILES-WEBB, D.P.H., D.T.M. & H. (CAMB.), OFFICIATING DIRECTOR OF PUBLIC HEALTH, 1925. NAGPUR: GOVERNMENT PRESS. PRICE RE. 1.

BOTH the climatic and economic conditions of the year were favourable to health. The rainfall distribution was satisfactory, crops well up to the average, no deficiency of food stuffs, whilst prices remained steady. In consequence the year was a healthy one and there was no widespread epidemic disease. These favourable conditions are reflected in the birth rate, 44.18 per mille, which was 5.62 above the quinquennial average; the death rate of 32.59 per mille, a figure 4.85 below the quinquennial average; and an excess of births over deaths of 11.59 per mille.

Yet the position is not as roseate as it sounds. "Owing to the action of the Legislative Council in refusing to vote any of the demands in the budget for 1924-25," runs the covering Government resolution, "the programme of sanitary schemes continued to be restricted during the year....Recurring grants of Rs. 40,598 for sanitary works were made....Of the total income of municipal towns in this province, 34 per cent. was spent on public health purposes, as compared with 38 per cent. in 1923, 46 per cent. in 1922, and 50 per cent. in 1921. The decreasing interest displayed by local bodies in public health measures is regrettable. Moreover the Director of Public Health reports that want of co-operation between the officers of the municipal committees and the executive officers of Government has led to considerable delay in the development of sanitary schemes in some towns. The local bodies would do well to realise that neither education nor medical relief nor any other public activity can flourish amidst squalid and unhealthy surroundings." Non-co-operation may be an ideal in a Utopia where there is no disease; in a province with the highest infantile mortality in India it is a disaster.

The infantile mortality during the year in the province was 235 per mille of living births, as compared with corresponding figures of 212 for the Punjab, 198 for the United Provinces, 184 for Bengal, and 78 for England and Wales. Some 52 per cent. of the total mortality in the province occurs among children under five years of age; one child in every three dies within its first year of life, one in every eleven within the first week of life. If the true meaning of such figures could only be driven home to the voting public, one might see a welcome revolution in public health matters in India. That strenuous efforts are made, no one can deny; but "any sustained advance in public health is dependent more on the activities of members of the public than on the introduction of new schemes by any department of Government." National Baby Week was held in some 40 municipalities during the third week in January and was very successful, but the holding of such an annual week is not enough; it should be followed up by the establishment of child-welfare centres in all the larger municipalities. In Nagpur the child-welfare centres already have a record of useful work to their credit. The infant mortality among 1,902 babies visited by the health visitors was 118 per mille, as against a figure of 182 per mille for 3,818 unvisited

babies; shewing an approximate saving of 70 lives per mille as the result of this activity. In other districts matters are also improving; in Jubbulpore there is one female assistant medical officer with four trained *dhais* in charge of the work, and 3,083 visits were paid. In Hoshangabad the hospital midwife visited 562 babies out of 568 births. In Saugor classes for *dhais* are held; whilst the Raipur municipal committee has decided to open a permanent child-welfare centre. In other municipalities, however, councillors are willing to fall into line, but are waiting for the hoped-for grant from the provincial government before commencing operations.

In an interesting analysis of the causes of this very high infant mortality, Colonel Stiles-Webb gives two fundamental factors as the causes; (a) ignorance of the principles of motherhood. This can only be dealt with by education, especially by the establishment of permanent child-welfare centres and the employment of health visitors, and in this connection he pleads that Indian ladies of standing will come forward with their very great influence and lend a hand; and (b) insanitation in all its forms, the alleviation of which forms the first duty of the Public Health Department, and which can be chiefly combated by the provision of pure water-supplies and of effectual surface drainage.

With regard to death rates in general, that for Mahomedans, 36.62 per mille, is very markedly above that for Hindus, 27.10 per mille, and this is attributed to the effects of the purdah system. The urban death rate, 37.29,—as usual—was greater than that for rural areas, 32.29. The town of Nandura in Buldana district reported the amazing death rate of 61.64 per mille,—partly at least attributable to plague.

Registration of vital statistics continues to be bad; apathy and indifference still prevail in most of the municipalities, where the committees take no interest at all in this important work. The matter is left entirely to the subordinate staff whose work is never checked. The practice of copying entries from each other's registers by the police and municipalities is always indulged in, and no steps are taken to check defaulters.

Of the chief causes of mortality, "fevers" heads the list with a mortality of 17.32 per mille; next come respiratory diseases, 2.67; dysentery and diarrhoea, 2.33; plague, 0.80; cholera, 0.70; and injuries, 0.47, a high figure due to the wild and jungly character of much of the country concerned.

Cholera.—The disease shewed a distinct increase on the figures for 1923; with 9,704 deaths, of which 2,964 occurred in August. (It is to be noted from the reports of the provincial Directors of Public Health concerned, that the year 1924 saw a distinct extension and increase of cholera from Eastern Bengal into Bihar and Orissa, the Central Provinces, and—via Kashmir—into the Punjab. The 1924 figures for the United Provinces have not come to hand, but, as our readers will recall, Colonel Gill has recently raised the very important question in our columns as to whether this may not represent the commencement of another world-wide pandemic, commencing—as usual—in Eastern Bengal, and possibly extending, as it has previously done, to the banks of the Mississippi). In the Central Provinces in that year Chanda was first infected by pilgrims returning in March from Benares. Buldana and Akola districts were also cholera centres during the year.

Vigorous anti-cholera measures were taken, and inoculation is gaining in popularity, as many as 8,887 persons having been inoculated during the year. Reports as to the different value of the essential oils' mixture, kaolin, and other lines of treatment give rather conflicting evidence. With regard to anti-cholera vaccine Colonel Stiles-Webb advocates a single dose of 1½ c.c. for an adult, or 1 c.c. for a child, in place of the usual two doses with a ten day interval.

Fevers.—Deaths from fevers numbered 240,944, but the only district to report severe epidemic malaria was Chanda. The Central Jail, Nagpur issued 91 lbs. more quinine than in the previous year, whilst the official price for quinine sulphate was reduced from Rs. 27 to

Rs. 24 per lb. The issue of cinchona febrifuge in place of quinine has been considered; but the former is not considered satisfactory as it is not standardised; a limited issue for experimental trial is being made to government departments only. Influenza of mild type was reported from many districts, but relapsing fever was almost completely absent,—only two cases having been reported. "Tick-typhus" occurred during the military manœuvres near Saugor.

Plague constituted the chief epidemic disease of importance during the year, the deaths totalling 11,081 as against 15,867 in 1923, and the infection being widespread. In Jubbulpore city a special advisory committee was formed, isolation hospitals opened, health camps organised, and inoculation centres established. A vigorous anti-rat campaign was started in August, and the epidemic which broke out in Meloniganj ward made only very slow progress during the rest of the year; the measures taken being almost sufficient to hold it in check.

No less than 54,305 persons were inoculated against plague during the year, and inoculation is now readily resorted to by the people in the presence of an epidemic. In Nagpur town a vigorous anti-rat campaign was carried out, and although plague was prevalent in several localities near the town, and four cases—3 imported and 1 indigenous—were reported within the town, yet the disease did not spread. The Deputy Commissioner writes that he considers that the anti-rat campaign saved the town. In Amraoti also a vigorous anti-rat campaign was carried on; "it is striking to compare Takarheda, a village of 1,628 souls with 262 attacks in three months, with Amraoti city with its population of 37,568 with only 153 attacks in three and a half months in the latter half of the year when plague broke out afresh in each place," writes the Civil Surgeon. In many other centres rat destruction was resorted to more or less vigorously.

"The concrete example of Nagpur," writes Colonel Stiles-Webb, "clearly shews that if a rat destruction campaign is to have any material effect in preventing plague outbreaks in towns, it must be systematic, vigorous and continuous. Hap-hazard methods not only are ineffective, but bring the whole system into disrepute Municipal committees must adopt a definite scheme on approved lines and continue it through the year for at least three or five years."

There were 31 epidemic travelling dispensaries at work in the province during the year; they visited 4,511 villages and treated 60,093 patients. When not engaged in dealing with epidemics, the staff of these travelling dispensaries is employed in public health propaganda work, inspection of schools and villages, and checking vital statistics. "They are doing useful work and are popular" writes Colonel Stiles-Webb.

Rabies.—Anti-rabic treatment centres were opened during the year at the Mayo Hospital, Nagpur and the Victoria Hospital, Jubbulpore. Of 355 dog-bite cases, it is reported that 306 were sent for anti-rabic treatment, of whom one died, 6 cannot be traced, and the 299 remain well and fit.

Leprosy.—Two hundred and fifty-eight patients were treated at the government and mission hospitals during the year; and an additional 174 patients at the Chandkhuri asylum by a special course prescribed by the Calcutta School of Tropical Medicine, consisting of injections of the esters of hydnocarpus oil and the use of chaulmoogra oil both externally and orally. A grant of Rs. 26,000 has been given to the asylum at Dhamtari to provide additional accommodation. Of reports by different superintendents:—The Superintendent at Dhamtari has been using "E. C. C. O." and "E. T. O."; but reports no definite results; the Superintendent at Mungeli reports satisfactory results in the treatment of 38 patients with sodium morrhuate; the Superintendent at Champa, using the ethyl esters of hydnocarpus oil, says that the results are most gratifying. The Civil Surgeon, Akola, reporting on the treatment of 71 cases, mostly of nerve type, with

"E. C. C. O." and hydnocarpates says that no improvement has been noted. "One tubercular case has been under treatment for about 18 months, but his condition is unaltered. He is an only son, and as his father is most anxious for his cure, he has attended regularly for treatment."

The sections on municipal and rural sanitation in this report make doleful reading. In Drug town the municipal area has not been cleared from rubbish, nor has disinfection of latrines, drains and cesspools been carried out satisfactorily, while the municipal committees have not been able to prepare a workable scheme for the improvement of the water-supply. With regard to Khurai and Deori, the Deputy Commissioner remarks "these municipalities are entirely apathetic in everything connected with improvements in sanitation, and so far as one can see, will continue to remain so until a miracle occurs by which the electors and their representatives begin to take a live interest in the welfare of the areas committed to their charge." In Wun town the inhabitants were driven to complain of the grossly insanitary state of the town during the last cholera epidemic, but it remains *in statu quo*. Of Akola town the Deputy Commissioner writes, "I consider the sanitation of Akola town is not quite so bad as it was last year, but it is still in a condition of which any other municipality might well be ashamed." In Jubbul-pore town a most remarkable economy has been effected whereby the sanitary staff have been set to work to do the tax-collecting in addition to their own duties, a development which is likely to lead to the failure of both undertakings.

One very satisfactory feature of the report is its account of the useful volume of work done in the medical inspection of schools throughout the province. In municipal areas 56,037 children were inspected, and 53,594 children in rural areas. Steps are taken to discover unvaccinated children, report on the spleen rates, discover physical defects and to advise teachers and parents. Finally very active health propaganda work is being carried on. The two Health Publicity officers appointed in 1922 visited many municipal centres and delivered some 200 lectures; the Health Publicity scheme has now been made a permanent one, and the two present officers, Drs. Mehta and Mangrulkar have been confirmed in their appointments.

Colonel Stiles-Webb's report is one of great interest. It should be added that the office of Director of Public Health, C. P., was held during the year 1924 by Lieutenant-Colonel T. G. N. Stokes, M.N., I.M.S., and that the report is compiled from his records and notes.

MUNICIPALITY OF COLOMBO. REPORT OF THE MEDICAL OFFICER OF HEALTH FOR THE YEAR 1924. MUNICIPAL PRINTING OFFICE, COLOMBO.

SITUATED as it is in a tropical and almost Indian climate, and being the centre of the Eastern maritime trade, the annual health reports of Colombo are always interesting reading. The report for 1924, by Dr. W. Marshall Philip, profusely illustrated and full of interesting matter, is no exception to the rule.

The year was exceptionally wet, with a total rainfall of 122 inches, some 40 inches above normal, whilst the mean average temperature for the year was 81° F. The estimated population was 253,226, or if the correction considered necessary by the census officer be considered, probably about 280,000. Singhalese predominate,—118,854,—but the population is a very mixed one, containing large elements of Tamils, Moors and Malayas, with some 3,000 Europeans. The birth rate was 27.2 per mille, a figure considerably above the decennial average of 26.4. The Malay birth rate has shewn a remarkable increase of recent years, probably due to better registration among this community, and the registering of all births resulting from intermarriage of Malay with other races as Malay children.

The death rate was 29.3 per mille,—or if checked by the correction for the census figures, 24 per mille. In all 7,429 deaths were registered, of which 1,107 were

due to pneumonia and bronchitis, 801 to dysentery and diarrhoea, no less than 722 to tuberculosis, and 316 to enteric and continued fevers. Owing to the exceptional care with which the Colombo figures are gathered, one concludes that this represents approximately the conditions prevalent in a large seaport in the tropics, and the tremendous incidence of tuberculosis will not be passed by without remark. The Malays shewed the greatest death rate, 35.3, but this is probably an exaggeration, as many pseudo-Malays are included; on the other hand the low figure of 12.9 for the European community is certainly too low, as many when mortally sick proceed home to die, and owing to retirement in middle age.

The infantile mortality was 239 per mille of live births, as compared with a decennial average of 254. Deaths from tetanus neonatorum have shewn a remarkable decline from 28 per mille in 1908-12 to 3 per mille in 1918-22,—the war years, as being exceptional, being excluded. On the other hand the deaths from congenital syphilis have shewn a corresponding increase from 3 to 5 per mille. The former decline must be attributed to child-welfare and ante-natal measures; there are 11 municipal health visitors and 7 municipal midwives, also a government lying-in home, a hospital for women, a hospital for sick children, three free milk depôts, and a small creche. The question of establishing an up-to-date child-welfare centre is receiving attention.

Of the principal diseases, the incidence of pneumonia has shewn a slight but definite decrease on the previous year. Phthisis is rampant, and a most serious problem; "the population, not only of Colombo, but of the whole island, is very heavily infected," the average death rate in Colombo for 1924 being 2.69 per mille. A very informative spot map shews the exact correlation between phthisis incidence, overcrowding and slum areas. There are government isolation hospitals for small-pox, writes Dr. Philip, but for this far more terrible scourge a single hospital with accommodation for 350 patients is all that is available; at least double such accommodation is required. (In Calcutta the available accommodation is about 25 beds).

Cholera is not endemic in the island and only one imported case occurred. Enteric fever is mainly of a mild type, and many non-fatal cases must escape notification, to constitute further infective foci. Small-pox is almost negligible, 9 cases during the year, of which several were imported; 6,887 births were recorded during the year with 5,784 primary vaccinations and 1,398 re-vaccinations,—a very satisfactory state of affairs.

Plague however constituted a serious question during the year,—148 cases with 140 deaths having occurred. For the first time in the history of plague in Colombo primary pneumonic plague appeared, fortunately limited to a series of seven cases. Vigorous measures were taken and the outbreak promptly subsided, but its occurrence is not without significance, and a special and detailed report by Dr. Aserappa is appended. A total of 137,406 rats were killed during the year, and 29,429 of them examined, which shewed a plague incidence of 0.29 per cent.

Malaria is not a very important problem in Colombo, 1,627 cases having been treated during the year, and 77 deaths from malaria having been reported. Legislation rendering the breeding of mosquitoes a statutory offence has been refused, however, and preventive work is much handicapped; epidemic conditions prevail from time to time and the possibility of severe epidemics cannot be negated.

Administration.—Food inspection is still in an unsatisfactory state, and the appointment of a whole-time food inspector for the town is urgently needed. There were 46 dairies registered at the end of the year, but the majority of them are unsatisfactory. The Colombo Ladies' League offer prizes for the best run dairies, with the result that newly registered concerns begin well, but end badly, although they still continue to shew their certificates of merit. The apathy of the

public and the existence of numerous unlicensed vendors are largely to blame. Some idea of the activities of the public health staff in this connection may be gained from noting the fact that 29 licensed vendors were prosecuted during the year, all successfully, as the result of 1,051 inspections made; whilst 224 unlicensed vendors were prosecuted and 214 of them convicted. The unlicensed vendors constitute a particularly difficult problem; the licensed vendors have more or less to conform to sanitary rules; the unlicensed ones take refuge in the compounds of Europeans and others who wish to obtain a cheap milk supply and evade all rules. A useful list of registered dairies and vendors, on p. 35 of the report, should go far to check this abuse.

Bakeries are more satisfactory than dairies on the whole, and better run. Here again a list of registered bakeries is given for general information. There has been a general improvement in the standard of eating-houses, as the result of frequent inspections, whilst the condition of the aerated water factories is on the whole satisfactory.

The question of the ice supply was bacteriologically investigated during the year by Dr. L. F. Hirst, Municipal Bacteriologist, and his special report on pp. 72 and 73 is of general interest, and applicable to Indian conditions. Three factories were investigated, all of which use the filtered town water-supply. In general it may be said that the ice is manufactured under entirely suitable conditions, is handled only mechanically until it is loaded into the delivery vans, and up to this stage is bacteriologically satisfactory. During the process of retail distribution, however, gross contamination may occur, and the chief source of contamination is the commercial sawdust in which the ice is packed for transport. Bacteriological examination of the sawdust gave counts exceeding 100 million organisms in 3 gms., and it is apparent that some species of lactose-fermentors are capable of rapid multiplication in damp moist sawdust. It is difficult to provide a substitute for sawdust; asbestos wool has been tried but is not commercially practicable. For the present, it may be said that the ice as it leaves the factories is bacteriologically satisfactory, but it must be most carefully washed free from all traces of adherent sawdust before it is safe to use, whilst ice-boxes containing sawdust require special attention. Contrary to popular belief, experiments shew that the addition of whisky to the iced soda does not inhibit the bacteria.

(This problem is one of considerable importance in every large Indian city, and conditions are presumably analogous to those in Colombo. The reviewer recalls in 1908 seeing large blocks of ice covered with sawdust being brought into a hotel in Poona at lunch time; they were washed, it is true, but in the most filthy water imaginable standing stagnant in a tank in the hotel garden. The moral is that ice must be thoroughly washed with cold boiled water before use. The Colombo report does not mention the use of blankets for wrapping ice, but the reviewer can recall an instance where some of the coolies at an ice factory used the blankets used to wrap up the ice for warming cholera patients among the personnel concerned.)

Dispensaries.—The four free municipal dispensaries continued to do good work among the poor; the numbers treated being 19,266 at the Slave Island dispensary, 17,073 at St. Paul's dispensary, 11,755 at Maradana dispensary, and 13,071 at Modera dispensary.

Housing.—Only minor improvements were carried out during the year, but a special report on the slum areas in Colombo was presented to government. "This is not a report upon infant mortality," writes Dr. Philip at the end of his special report, "but one cannot refrain from mentioning overcrowding in the slum areas as being one of the most important factors responsible for the set-back which has occurred during the last few years in the previously steady decline in the infant mortality in the town as a whole.....I would urge the paramount importance of measures being adopted at

the earliest possible moment to increase the housing accommodation for the poorer classes who now reside in these grossly overcrowded slum areas." And maps shewing the close correlation between slums, overcrowding and infant mortality lend point to the appeal.

Report of the Municipal Bacteriologist.

Annexure A to the report is the report by the Municipal Bacteriologist, Dr. L. F. Hirst, M.D., whose work is not unfamiliar to our readers. It is a special report full of interest to the laboratory and research worker.

In the way of general routine work 1,296 clinical specimens were examined, and a gross total of 37,964 specimens in general public health bacteriology; of 29,429 rats examined 87 proved to be plague infected. In connection with the previously mentioned outbreak of pneumonic plague *B. pestis* was obtained in pure culture from the sputum of one patient, and from lung juice drawn at post-mortem on a second. The evidence goes to shew that transition of bubonic plague to pneumonic plague may occur through the agency of a bubonic case which develops secondary pneumonia. The pneumonic cases appeared during the hot weather, a striking anomaly in the light of general experience in other countries. The sputum of a typical case of septicæmic plague in Colombo contains abundant plague bacilli, but climatic conditions in the tropics are usually unfavourable to their survival outside the human host.

On the afternoon of the 8th November, 1924 a social gathering was held at the Post Office Sports Club, where a variety of refreshments was served. During the following 24 hours no less than 77 of those who had attended this fell ill with severe gastro-intestinal symptoms, but fortunately all recovered. The only article of diet partaken of by all was the ice-cream, but none of the original sample which was suspected was available for examination. Thirteen other specimens from the refreshments used gave negative results; whilst the faeces of the four individuals who had taken part in the preparation of the ice-cream also gave negative results.

The faeces of one of the patients, however, yielded a culture of *B. artrycke*; and three mice fed with this organism died of gastro-enteritis, the same organism being recovered from their stools. Sera were obtained from 8 of the convalescent patients and agglutinated *B. artrycke* (Lister Institute strain) at titres up to 1 in 1,200 and the locally isolated organism in titres up to 1 in 1,000. (As Dr. Hirst remarks in passing, it is to be noted in this connection that recently isolated strains do not usually exhibit full agglutinability, as is also the case with the Flexner group of dysentery bacilli). The outbreak therefore was clearly due to *B. artrycke*, and instances are quoted of other similar outbreaks from the literature. It is to be noted that flies were very troublesome in the house where the ice-cream was prepared.

On the veterinary side, Dr. Hirst gave evidence before a committee appointed to enquire into the spread of rinderpest in Ceylon, and pleaded for the extended use of the double inoculation method for the immunisation of susceptible cattle. In February an outbreak of infectious pneumonia occurred among a consignment of goats imported from Karachi, and a pasteurilla organism was isolated.

The main portion of Dr. Hirst's report deals in detail with his researches on the spread of plague in Colombo, and is a section that we trust will later see wider publicity than in the columns of an annual report. This work was commenced some years ago, and followed on the finding of *Xenopsylla cheopis*, the plague-carrying flea in Colombo rats, first in 1914. The two species of rat prevalent in Colombo are *R. rattus* and *R. norvegicus*, the former being the more important. A systematic collection of rat fleas was made during the plague season from different areas in the town. The statistical results, analysed by mathematical methods, shew that there is the closest possible correlation between the regional

incidence of human plague in the different quarters of the city, and that of *X. cheopis*. In the old system of Dutch drains beneath the endemic area probably *R. norvegicus* predominates, and here temperature and humidity conditions are probably more favourable than elsewhere in the city for the survival of infected *X. cheopis*; further Dr. Hirst has found the same flea on the "musk-rat," *Pachyura carulea*, a known reservoir of plague-fleas in French Indo-China.

Summarising the results of his researches into the question since 1915, Dr. Hirst reports:—

(1) Attempts to carry plague from rodent to rodent with *X. astia* at room temperature during the plague season gave negative results.

(2) Similar attempts with *X. cheopis* were successful.

(3) Further, plague has been transmitted from rat to rat by *X. astia* in one experiment carried out under artificially reduced temperature; and *X. astia* has been found to behave as a "blocked" flea. It is comparatively easy to obtain a heavy growth of plague bacilli in *X. astia* fed upon infected rats, but these blocked fleas have a low vitality and bite rats but feebly at tropical temperatures.

(4) At room temperature during March, under climatic conditions particularly unfavourable to plague transmission to man, the infection could nevertheless be continuously transmitted from rat to rat by *X. cheopis*.

(5) As regards the relative virulence of plague bacilli in the stomach of *X. astia* and *X. cheopis*, there seems to be no difference.

Finally, in conclusion, both species appear capable of plague transmission. But under such tropical conditions as are encountered in India and Ceylon, *X. cheopis* is the more efficient and important vector of the infection.

Where does the *X. cheopis* come from, seeing that its occurrence in Colombo was first noted in 1914? The answer is that it is probably an imported flea, developing chiefly in the vicinity of grain stores, and possibly assisted in its development and distribution by the presence of the old Dutch underground drains in the endemic area. In outlying districts of the town, non-infected, the *cheopis* constitute only some 1 or 2 per cent. of the rat fleas present; in the grain-store areas its percentage rises to 50 to 70 per cent, and during an epizootic of plague among the rats to 80.3 per cent.

The endemic plague area in the town itself is not particularly congested, and is relatively free from enteric fever and other intestinal disorders due to insanitary conditions. As in India, the association between plague prevalence and housing conditions is indirect. Further investigation is called for; but it is to be noted that plague reached Rangoon in 1905, but it was not transferred to Colombo till 1914. The rainfall during this interval was deficient and climatic conditions probably unsuitable for the transference of *X. cheopis* to Ceylon and Southern India.

By way of remedies, disinfection of imported grain has been suggested. "Before *X. cheopis* appeared the amount of grain stored in the endemic area was many times greater than at the present time. No improvements had been carried out in the method of grain storage. The whole endemic area must have swarmed with rats. Yet there was no plague. . . . Since 1915 the whole of the rice has been withdrawn from the endemic area and stored in government granaries. Many of the private stores have been much improved, and a vigorous anti-rat campaign is continually prosecuted in the endemic area. Yet plague recurs each year. . . . The grain has been removed from the vicinity of Sea Street. . . . Plague and *X. cheopis* remain; probably they will continue to do so till underground communication with the adjoining district is cut off."

The report also records the result of certain preliminary experiments to determine the relative viability and biting proclivities of male and female fleas of the two species. The whole of this section of Dr. Hirst's report is full of interest; it should be read in the original by all interested in experimental work on plague transmission.

Annexure B to the report is by Mr. Alexander Bruce, the City Analyst. The milk supply is still unsatisfactory; nearly 40 per cent. of 938 samples tested were found to be adulterated, the maximum adulteration being 76 per cent. Experiments are in progress directed to ridding the water-supply of dissolved iron and to aerate it after filtration. The supply on the whole however is satisfactory.

Correspondence.

FITZSIMONS' ANTIVENOMOUS SERUM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Since the publication of my notes on the treatment of cobra bite with Fitzsimons' antivenomous serum, I have been receiving numerous enquiries as to where this serum can be had. As it is impossible to reply individually to so many letters, I would be much obliged to you, if you will kindly inform the readers of the Gazette that, though we obtained our supply of the serum from Messrs. Smith, Stanistreet & Co. of Calcutta, it is at present not available in India.

The serum can be obtained direct from the manufacturer, Mr. F. W. Fitzsimons, Director, "Snake Park," Port Elizabeth, South Africa. I have written to Mr. Fitzsimons to arrange that it may be easily available in India.—Yours, etc.,

A. C. BHARADWAJ, L.M.P.,

House Surgeon, King Edward VII Hospital

BENARES,

22nd December, 1925.

IODOFORM POISONING.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Gaya Prasad, aged 40. Hindu male, Kayisth by caste, of Sambhanli Station, E. I. Railway, was brought to my dispensary in a very miserable plight. He had a big ulcer in his left leg and a large area of acute eczema and pustulation around it. Pus was running from the sore, like water from a spring, and the whole leg was swollen from the knee to the toes. There was a similar ulcer on the lobe of the left ear, with similar features. The face was swollen and the left eye closed with swelling. Fever was also present.

On questioning the man, he said that a month previously he had been advised to use iodoform for a small ulcer on his left leg, also for some local irritation in the left ear. As the result of indiscriminate use of iodoform, in a month's time the patient had developed the condition described.

I gave both lesions a thorough washing with Condy's lotion and applied lint soaked in a lotion of potassium permanganate, zinc oxide and lead, but to no avail. Next day I scraped the ulcer on the leg, washed it thoroughly with saline, and bandaged the affected parts with an ointment of calomel, zinc oxide, boric acid, camphor, sulphur and vaseline. Diuretics and diaphoretics were given, and twenty days later the patient was discharged cured.

My object in writing to you is to draw attention to the dangerous and indiscriminate use of iodoform by itinerant quacks, who get hold of English medicines and use them freely without any knowledge of their dosage or proper use.—Yours, etc.,

HARDEO SINGH, L.M.P.,

GARHURGETER DISPENSARY,

MEERUT DISTRICT.

22nd December, 1925.

THE PRICE OF SANTONIN.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Comment was made in a recent issue of your journal on the price of santonin. Your readers will be interested to know, that we have recently announced a substantial reduction in the price of this well-known drug. Our reduced price for wholesale quantities is equivalent to about 29s. 9d. per oz., or about 1d. per grain. Our new scale of prices and a full explanation have appeared in the *Chemist and Druggist* of November 28th and December 5th 1925.—Yours, etc.,

THE EASTERN & RUSSIAN TRADING
CO., LTD.

ESSENTIAL OILS' CHOLERA MIXTURE.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—With reference to the article on "Cholera at Goalundo Ghat Hospital" by Dr. W. J. Marshall in your issue for January 1926, p. 4 in which he states that the "essential oils' cholera mixture" is too pungent and irritating for general use, I desire to point out that although the mixture is undoubtedly pungent and may in some cases be somewhat irritating, such facts are too trifling for serious consideration where life and death are in the balance as is the case in cholera.

The characteristic pungency of the mixture may however in a considerable measure be obviated by administering half-drachm doses of the mixture every quarter of an hour in an ounce of water, instead of drachm doses, every half hour, in half an ounce of water as recommended in my original paper.

Sucking a small piece of ice after administration of the mixture also tends, where available, to minimise the tendency to vomiting which is a constant and inseparable feature of the disease.

The dose originally recommended by me was designed for field use where neither medical aid nor intelligent nursing was available, and where it was imperative if success was to be obtained in a majority of cases that the greatest possible quantity of the mixture should be administered in the shortest probable time, notwithstanding the increased risk of vomiting thereby incurred.

In making this recommendation I was influenced by the consideration that if half-drachm doses every quarter of an hour were advocated the patient would almost certainly in practice through want of proper nursing get half-drachm doses every half-hour instead of every quarter of an hour as intended, with the consequent increase in the risk of collapse from delay in administration of a sufficient quantity of the mixture to prevent it.

I also desire to take this opportunity to point out once more that the "essential oils' mixture" is in no way a rival of saline injections as a treatment for cholera, saline injections being a treatment for collapse and the "essential oils' mixture" a treatment to prevent it. Collapse having once set in, the time for administering the "essential oils' mixture" is in the great majority of cases over.—Yours, etc.,

GYMNEMA SYLVESTRE IN THE TREATMENT OF DIABETES.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—There is a creeper plant named *Gymnema sylvestre*, natural order *Asclepiadaceæ*, whose leaves when chewed after a few minutes remove the sweet

taste of sugar. This quality has been noted by Halliburton in his *Handbook of Physiology* and also by Dymmock, Khory, Kirtikar and others in books on the indigenous drugs of India. Halliburton considers this action as due to a selective action on tongue papillæ.

As the taste of salt was not affected by the leaves it was thought that the action might be a chemical or a biochemical one. Rough experiments with a little of the powdered leaves mixed with diabetic urine reduced the percentage of sugar in the urine as tested by Benedict's solution. Certain laboratory experiments made by Professor Kolhatkar of the Ferguson College, Poona, showed that there was a chemical action. These tests were made with standardised glucose solution and Fehling's solution.

It was thought that if the action was a chemical one, the leaves might be useful in diabetes mellitus in reducing the amount of blood sugar and the urinary sugar. The leaves were given as a powder in half to one teaspoonful doses. It can also be given as a decoction (1 oz. powdered leaves are boiled with 10 ozs. of water till the quantity is reduced to 4 ozs.: 1 oz. for a dose, Khory). Some striking results were obtained in that the sugar in the urine was greatly reduced or totally disappeared.

Dr. Mhaskar at the Haffkine Institute, Bombay, is doing some experimental research work on it with encouraging results.

In one case the powder has been tried in a case of diabetic carbuncle as a dusting powder with apparently good results.

This note is written in order that medical officers may give the drug a wide-spread clinical trial in the treatment of diabetes, as the antidiabetic properties of this plant seem to have been overlooked hitherto.—Yours, etc.,

K. G. GHARPUREY,

Major, I.M.S.,

Civil Surgeon, Sholapur.

4th December, 1925.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel H. Hallilay, M.B., I.M.S., offg. Civil Surgeon, Simla, West, is appointed to hold charge of the duties of the Civil Surgeon, Simla, East, in addition to his own, during the absence on leave of Lieutenant-Colonel MacMillan.

Lieutenant-Colonel J. B. D. Hunter, O.B.E., I.M.S., an Agency Surgeon is posted as Residency Surgeon, Rajkot with effect from the 29th December 1925.

The services of Major F. A. Barker, C.B.E., I.M.S., have been placed temporarily at the disposal of the Government of the Central Provinces for employment as officiating Inspector-General of Prisons, Central Provinces with effect from the date on which he assumed charge of his duties.

Major S. S. Sokhey, I.M.S., is appointed temporarily to the Medical Research Department and posted as supernumerary officer at the Haffkine Institute, Bombay, with effect from the 18th August 1925. His services are placed at the disposal of the Government of Bombay, for employment as Officiating Assistant Director of the Institute with effect from the date on which he assumes charge of the duties of the appointment.

The services of Major C. McIver, I.M.S., are placed permanently at the disposal of the Government of Assam.

Major E. W. O'G. Kirwan, M.B., F.R.C.S.I., I.M.S., on being relieved of his duty as officiating Superintendent,

Campbell Medical School and Hospital, has been placed on general duty at the Medical College.

LEAVE.

Lieutenant-Colonel D. Heron, C.I.E., I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months and on half average pay for 4 months, under Fundamental Rules, with effect from the 5th November 1925.

Captain S. N. Mukerji, I.M.S., officiating Civil Surgeon, Chittagong, is allowed leave on average pay for the period from the 18th December 1925 to the 2nd January 1926, both days inclusive.

PROMOTIONS.

Major to be Lieutenant-Colonel.

N. S. Sodhi, M.C. Dated 1st March 1925.

(Army Department Notification No. 1253, dated the 11th September 1925, in so far as it relates to this officer is cancelled).

Captain (now Major) H. M. Inman, I.M.S., is granted the acting rank of Lieutenant-Colonel from 1st October 1917 to 25th July 1918 whilst employed with the East African Force.

Lieutenants to be Captains.

Moore Taylor, M.B., I.M.S. Dated 18th October 1925.

C. V. Falvy. Dated 17th October 1925.

RETIREMENTS.

Lieutenant-Colonel J. H. Hugo, D.S.O., M.B., I.M.S., with effect from the 17th July 1925.

Captain J. F. Holmes, I.M.S. (since deceased), with effect from the 12th November 1924 on account of ill-health.

RELINQUISHMENT OF RANKS.

With reference to previous notifications, the under-mentioned officers of the Indian Medical Service relinquished their acting or temporary ranks, with effect from the dates specified:—

Major E. E. Doyle, D.S.O. Dated 2nd February 1921 (forenoon).

Major R. B. Nicholson, O.B.E., M.C. Dated 1st August 1918 (afternoon).

Major T. A. Hughes. Dated 13th July 1920 (forenoon).

Major J. A. Sinton, V.C., O.B.E. Dated 31st July 1920 (forenoon).

Major J. C. Bharucha. Dated 16th September 1919 (forenoon).

Major P. B. Bharucha, D.S.O., O.B.E. Dated 16th July 1920 (afternoon).

With reference to previous notification, Captain (now Major) T. D. Murison, I.M.S., relinquished the temporary rank of Major on ceasing to hold the appointment of Deputy Assistant Director of Medical Services (Sanitary) of the late Karachi Brigade, with effect from the 26th October 1920 (forenoon).

NOTES.

THE THIRTIETH CHEMISTS' EXHIBITION IN LONDON.

THE Thirtieth Chemists' Exhibition will take place on May 10th to 14th, 1926, at the Holland Park Hall, London, W. The exhibition was established in 1896, and has filled a very important need to the practising pharmacist in enabling him to see all the goods he sells and the apparatus, etc., which he uses in his profession under one roof. Last year's exhibition marked a record, and the much larger hall enabled the promoters to introduce a number of novel and interesting features. These will be continued and extended next May. The management is always delighted to welcome visitors connected with the drug trade from the Dominions and Colonies, and such gentlemen will be admitted on presentation of their professional card. The exhibition is organised by the *British and Colonial Pharmacist* and is strictly confined to the trade.

"PONNDORF" CUTI-VACCINATION.

WE have received from Messrs. H. R. Napp, Ltd., 3 and 4, Clements' Inn, Kingsway, London, W.C.2, a small brochure dealing with the "Ponndorf" method of cutaneous vaccination in prophylaxis against and in the treatment of tuberculosis of all types. This method is now in its second decade of trial, and many German reports speak of it very highly indeed. It has recently been shewn by the work of Besredka and others that we have neglected the skin too much as a system of the body capable of producing immune substances; in vaccination the principle has been made use of in universal vaccination since the days of Jenner; what is not realised however is that immunity to other infections may result from vaccination of the skin with other antigens. Further, in such vaccination the dosage can be very exactly controlled, the exact degree of reaction noted for future guidance, and the dose increased or decreased accordingly.

In the "Ponndorf" method the tubercular antigen is put up as "virus A" in sealed capillary tubes. The preliminary test, which is advisable in all cases, and absolutely essential when dealing with pulmonary tuberculosis, is to scarify the skin lightly—as in vaccination—and apply one drop of the virus over a scarified area about 1 cm. square. The degree of reaction is noted, and if not severe the preliminary vaccination may be followed by a course of vaccinations, not exceeding 18 or so within one year. In "virus B" a preparation is put up which—in addition to the tuberculin element—also contains antigens from the secondary micro-organisms associated with phthisis and chronic bronchitis.

In general the reports quoted in the brochure speak of the special value of the method in the sphere of early diagnosis and treatment of early cases of tuberculosis of all types. In cases of phthisis of the second stage very good results are reported; but cases of the third stage appear to be unsuitable, except where the infection is walled in by fibrosis. The two viruses are put up in sealed capillary tubes, and are stated to keep in any climate.

The same firm also issue "Xifal-milk," a sterile milk-protein combined with a vaccine of low virulence. In ampoules of 2 c.c. and 5 c.c. for hypodermic administration in cases of epilepsy, encephalitis lethargica, infantile paralysis, and gastric and duodenal ulcer. In these diseases it is stated that good results follow a course of such injections.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

THE PATHOGENIC EFFECTS OF HELMINTHIC INFECTIONS.

By ASA C. CHANDLER, M.S., Ph.D.,

*In Charge, Hookworm Research Laboratory,
Calcutta School of Tropical Medicine.*

THE question of the pathogenicity of various helminthic infections, and particularly of hookworm infections, has long been a matter of dispute. The general opinion is that hookworm infections are as a rule harmful, *Ascaris* infections much less so, and *Trichuris* infections practically innocuous. In support of this view, particularly with respect to hookworm infections, there is a great mass of evidence in the form of clinical observations and effects of treatment on individuals and collective groups in schools, estates, industrial institutions, etc. The majority of these observations have been made on people of the white race, and without reference to the intensity of the infections. The effect of light hookworm infections is a matter of considerable difference of opinion. Lane (1917) summarizes the situation as follows:—"Opinion regarding hookworm infection has constantly passed through three stages in the individual or the community. The first of these phases is an unreasoned conclusion that disease and death occurring in an infested subject are caused by that infestation. The second phase, based on the realization that in the tropics more persons than not are infested and that they appear to be in normal health, lays to the credit, or discredit, of the parasite no ill effects, unless the infestation be a massive one and makes the host obviously a sick man. The third stage consists of a realization, based on careful records of widespread improvement in health and energy following the freeing of infested persons of their infestation, that even mild infections have an influence for the bad on their victims." Lane quotes passages from reports of the Rockefeller Sanitary Commission which he says show quite clearly that the officials of the Commission started with their minds satisfied that mild infections were a matter of no moment to the host, and ended up thoroughly convinced that even very mild infections constitute a grave handicap to the unfortunate harbourers. Lane further quotes letters from managers of tea estates in the Darjeeling districts, where there is widespread but for the most part mild hookworm infection, which express satisfaction and in some cases enthusiasm over the effects on the health of the coolies of anti-hookworm treatment. Similar reports of improved health and augmented efficiency have been recorded from many different industries in many parts of the world.

It must be pointed out, however, that most of these mass observations add little to our knowledge of the effect of *light* hookworm infections, since all grades of infection are grouped together, and improved health and efficiency in a comparatively small number of heavily infected individuals or of a few especially susceptible individuals in the entire group might be sufficient to produce the observed improvement. Clinical observations on individuals have repeatedly shown that individual susceptibility is an important factor, and that the number of worms necessary to produce an evident effect on health may vary enormously. Ashford (1913) for instance, states that in Porto Rico many cases containing more than 1,500 worms showed little if any anæmia. Darling, Barber and Hacker, from their studies in Java, came to the conclusion that 250 worms on the average cause measurable loss of hæmoglobin, and think that it is reasonable to assume that 50 worms would cause 1/5th as much, whether or not their effect was counter-balanced by non-interference with reserve powers of the host by other causes. These authors concluded that a given number of worms would on the average cause more loss of hæmoglobin in women than in men, and more in children than in women, and that their effects are accentuated by weakening of reserve powers by malaria, malnutrition, overwork or other causes.

In my own study (1925) of 100 individuals in the Alipore Central Jail, 67 of whom were lightly infected with hookworm, but only six of whom had more than 1,000 eggs per gram of faeces, no difference in the hæmoglobin percentage between infected and non-infected individuals could be found. Mhaskar and Kendrick (1923) found a similar lack of correlation between hæmoglobin content and hookworm infection in light cases in Madras. Megaw (1920), on the other hand, in a study of over 4,500 jail inmates in various parts of the United Provinces (India) found a distinct correlation between the state of health, as shown by the prisoners' history sheets, and the degree of infection as determined by egg counts.

The most interesting recent contribution to this subject is a paper by Gordon (1925), on "The Effect of *Ancylostome*, *Ascaris* and *Trichuris* Infections on the Health of the West African Native," in which he reports some interesting and significant work based on a study of 137 African natives in Sierra Leone. The subjects included 49 youths averaging 18 years of age, attending school; 40 city police of all ages from 23 to 50; and 48 gaol prisoners of all ages from 17 to 49. Examination of these natives was carried out by the officers in charge of them with respect to the following characteristics:—(1) Physique and general fitness, as determined by a physical examination; (2) mentality, as determined by mental alertness and ability to learn; and (3) energy, as determined by the keenness with which an individual attempted any

mental or physical task allotted to him; the men were placed in order of merit in A, B or C class in each of these three categories. In addition two other tests were made in the laboratory; (1) hæmoglobin percentage, as determined by the Tallquist scale, and (2) presence of albumen or casts in the urine.

The degree of infection in these individuals was determined by the Stoll egg-counting method, without knowledge of the status of the individuals with respect to other tests. Careful analysis of the correlation between the degree of infection and the classification according to each of the above tests was made. In spite of the fact that many of the infections were very heavy (12 out of 114 having an average of more than 10,000 eggs per gram of fæces) no significant correlations were found in any case except the "energy" classification. There was no noticeable effect of *Ancylostome* (*Necator*), *Ascaris* or *Trichuris* infections on hæmoglobin percentage, physique and general fitness, mentality, or presence of albumen or casts in the urine. On the other hand the figures suggest the possibility of some association between hookworm infections of more than 15,000 eggs per gram of fæces, and the low standard of energy observed in such cases; the small number studied of such intense infections, however, makes it obvious that further work must be done to justify conclusions. Dr. Gordon is careful to state that his work deals solely with the West African male native and applies only to that race. It is certain that the white race is far more susceptible than the negro race; I have had occasion to observe this on numerous occasions in the Southern United States. Gordon points out that this tolerance may be shared by some at least of the Indian races, judging by hæmoglobin tests made by Mhaskar and Kendrick in Madras and Chandler in Bengal, but he overlooked Megaw's significant work in the United Provinces, referred to above.

It is unfortunate that Gordon did not include some tests of physical and mental endurance in his examinations since this would appear to be more important than short duration tests of mental and physical keenness and energy. There can be little question but that hookworm infection does cause severe anæmia in the white race and recent investigations by De Langen (1924), suggest that the effect is caused by a direct toxic effect on the blood-forming organs. The ability to make good an injury to the blood system, with the attendant results on other systems, may be sufficient so that no evident effect is present, yet a certain amount of energy and vitality must be used up to constantly repair the damage done, and as a result it is readily conceivable that resistance to fatigue, exhaustion and disease may be proportionately lowered. Up to a certain point the repair can keep pace with the damage, so that there is no hæmoglobin reduction; only when the infection is sufficiently heavy so that the repair cannot keep pace with the injury or when the reserve

power is weakened by other causes, is there any evident anæmia. It would appear from Dr. Gordon's work that this point is not reached nearly so quickly in the negro as in the white race. It seems to me not improbable that this may be associated with the development of a racial immunity—an ability to cope with the toxic effects of the parasite by some means not understood—resulting from age-long association of host and parasite, for it is a well-known fact that hosts and parasites do tend towards a mutual tolerance, where the injurious effects of one on the other are minimized. There seems to be good reason for believing that *Necator americanus* was brought to America by the African slaves, and it has always seemed to me significant that the adapted negroes showed much more marked tolerance than the unadapted whites.

If Dr. Gordon's observations on West African negroes do apply, even in a less degree, to Indian races, then hookworm infection in many parts of India may be considered practically harmless, for although a high percentage of people in India are infected, the infections are rarely heavy, as judged by egg counts, and of many hundreds of egg counts made in Bengal, not more than 10 per cent. exceed 1,000 eggs per gram of fæces. In one series of 127 cases in Eastern Bengal, 61 per cent. of whom were infected according to Lane's D.C.F. method, 46 per cent. of those infected had less than 100 eggs per gram, and not a single count exceeded 400 eggs per gram. It does not appear probable that if infections of 10,000 eggs per gram produce no noticeable symptoms in West African negroes, that infections of less than 1,000 eggs per gram would have an appreciable effect on Indians. However, until mental and physical endurance tests and accurate data on resistance to disease can be obtained, judgment on this point should be reserved.

THE TREATMENT OF MYELOMATA BY CURETTAGE AND AUTOGENOUS CANCELLOUS GRAFTING.*

By J. B. HANCE, O.B.E., M.B., B.Ch. (Cantab.), F.R.C.S.E.,
MAJOR, I.M.S.,

*Principal Medical Officer, Raj Marwar, Jodhpur,
Rajputana.*

THE treatment of myelomata by the method to be described was, as far as the writer can discover, first brought to the notice of the profession by Mr. A. H. Todd(1), who employed it with conspicuous success in the case of a myeloma of the outer condyle of the femur. Few who were privileged to hear Mr. Todd's description of his case, and to see his skiagrams can have failed to be impressed with the great possibilities of this form of treatment, in restoring both symmetry and function to the part affected, and for the writer's part, it formed the inspiration of the treatment employed on the case hereunder recorded.

M. A., male, aged 40, applied to hospital on 28th October, 1924, for treatment of a swelling on the ulnar side of the right forearm, in its lower third, extending to just above the wrist.

Of healthy cultivating stock, his history revealed nothing noteworthy except that his left leg had been amputated 8 years previously at the seat of election for gangrene following on injury.

Three years previous to admission, the patient had noticed a swelling in the lower third of the ulnar side of his forearm which had slowly but steadily increased in size until its interference with the power and movements of his hand caused him to apply for relief.

On examination there was a swelling of the general size and shape of a goose's egg involving the lower third of the ulna. The hand was held pronated, supination being impossible, and attempts to elicit it caused the patient a good deal of pain. Egg-shell crackling was elicited over the tumour in its posterior part, and the integrity of the middle of the inner aspect of the shell was doubtful. A radiogram (fig. 1) revealed the distension and thinning of the shaft of the bone with the bony septa typical of myeloma. A marked feature was the limiting reactionary compact bone at the upper pole, and the lower end of the ulna appeared also to be free.

Operation: 7th November, 1924.—An incision 5 inches in length extending from the left anterior superior iliac spine backwards, parallel to and immediately below the outer lip of the iliac crest was made, and carried immediately down to bone. The periosteum with the overlying muscles was stripped downwards with a rugine and strongly retracted, exposing an area of iliac bone some 4 in. by 2 in. With a broad gouge and hammer as much of the outer compact

layer and underlying cancellous bone as possible was removed from this area and transferred to a warm bath of autoclaved normal saline kept as near body heat as possible. The muscles and periosteum were then replaced, the cut edges of the former being united with three interrupted catgut retaining sutures, and the iliac wound was closed with Michel's clips.

Gloves, masks and gowns were now changed and during this interval the right upper limb was exsanguinated with an Esmarch's bandage and broad tourniquet.

An incision was made 5 inches in length along the inner border of the right forearm between the flexor and extensor and carpi ulnaris, extending from 1 inch below the styloid process of the ulna nearly to the middle of the ulnar margin of the limb. This was cautiously deepened till the ovoid swelling was defined and it was seen that its inner central part to the extent of a six-penny piece was softened. The periosteum was

Fig. 1.

next incised, in the line of the wound but "ringing" the softened area, and, with the overlying soft parts, stripped outwards and securely packed off with gauze to avoid future contamination with growth tissue. The inner side of the tumour was next incised at the softened area and the opening enlarged with scissors and nibbling forceps, till every bit of softened bony shell was removed. The tumour material was scraped out with a sharp spoon, and the whole of the inside of the ovoid cavity thoroughly and systematically curetted till every trace of tumour tissue had been removed. The opening into the tumour was then enlarged by removing the whole of the ulnar side of its shell, leaving an oval gap. The shell was found to be limited above by dense compact bone and below by a thin layer of similar bone overlying the articular cartilage. The interior of the cavity was next carefully

* Note.—We are much indebted to the Editor, *Guy's Hospital Reports* for his kind permission to re-publish this article, which appeared in that journal for January, 1926.—Editor, I. M. G.

swabbed out with pure carbolic acid. The excess of the latter having been thoroughly removed with absolute alcohol, the cavity was swabbed over with ether, dried with a stream of warm air, and the fragments of graft removed from saline and placed into the cavity, and the walls of the latter crushed down on to them. It was found that the graft was not sufficiently large entirely to fill the cavity, so further crushing was performed, the soft parts unpacked and allowed to fall over the gap in the bone, and the wound closed by Michel's clips. Dressings having been applied, the hand was fully supinated and firmly bandaged upon a zinc "cock-up" splint, the tourniquet removed, and the patient returned to bed.

During the whole operation, Lane's technique for bone operations was rigidly adhered to, and the gloved hand never touched the wound. Instruments which had touched myelomatous tissue were discarded after use, and fresh instruments used after the sterilization of the tumour cavity. The tumour material was despatched to the Central Research Institute at Kasauli, where, by kind permission of the Director, it was examined by Major L. A. P. Anderson, I.M.S., whose report is as follows:—

"The sections of the material show the typical structure of a myeloma." Fig. 2 is a microphotograph showing the appearance of this tissue

Fig. 2.

on section. To enter into any discussion of the histology after the work of Burlend and Harries would be invidious, more especially as the method of removal of the myelomatous material precluded any serial sectioning. Suffice it to remark that study of these sections offers striking confirmation of the observations of these authors as to the appearance and staining reaction of the giant-cells and the genesis of the spindle cells.

Hæmorrhage was controlled by firm bandaging which was cautiously loosened after 24 hours, and movements of the fingers were encouraged from the start. The clips were removed in two stages on the eighth and tenth days. On the latter

occasion, a little serous discharge from the centre of the wound occurred. Forty-eight hours later when next dressed, there was none, and the wound healed by primary union. Gentle massage was then instituted and finger movements increased with daily active and passive movements of the wrist. After a month the splint was removed for an hour daily and active movements progressively increased, with special attention to pronation and supination. After two months the "cock-up" splint was replaced by a straight splint to the wrist, and continuous active movements and performance of light tasks encouraged; and the patient left hospital with free wrist movement and wearing a wrist splint on 24th January, 1925.

After four months all splinting was dispensed with, and the patient advised to use the hand for light tasks. Radiograms taken 1, 2, 3, 5, and 7 months after operation respectively, show the progress of the graft. Figs. 3 and 4 show the conditions present 7 months after operation.

Fig. 3.

Especially noteworthy in the radiograms taken is the tendency shown by the new bone progressively to revert to the normal outline, thereby bearing out the graphic phrase of Sir Arbuthnot Lane that "the skeleton is the crystallization of lines of force." At seven months after operation the patient reports that the right hand and arm is but little weaker than the left, and, as shown in Figs. 5 and 6, he has full pronation and supination, while an idea of power may be gained from the fact of the ease with which he is holding up a large earthenware pot full of water.

Remarks.—It would appear that this form of treatment of myeloma has not yet received the attention which it deserves. Diagnosis of the

condition having been established and the disease being confined to bone, conservative treatment is the obvious indication. Rowlands and Turner(2) quote V. Moseitig and others as having

Fig. 4.

Semi-pronation showing tendency of new bone to assume normal outline.

extensively used various fillings such as iodoform wax for the filling of bone cavities, but only in cases of caries, and their criticism of these methods is that "most of them have proved

Fig. 5.

failures." These authors make no reference to this treatment being applicable in myeloma. Burlend and Harries(3) in a most instructive article describe the treatment of a white myeloma

by a boiled heterogenous graft. Such, however, according to Trethowan(4) neither live nor proliferate, acting merely as a scaffolding—a contention substantiated by the radiographs published by the two former authors. Carson(5) refers pessimistically to the treatment of myelomata by homologous grafts from a "recent amputation or from a corpse." The pessimism prevailing as to the success of wax fillings, heterogenous, and homologous grafts is scarcely surprising in view of the facts that they are inert substances, which if inserted with due regard to asepsis can at best but act as scaffoldings. Trethowan(6) in laying down the principle governing the grafting of bone lays stress on the advisability of an autogenous graft, but the same author states that the breaking up of the graft has no advantage. Todd's case, cited above, and the one here recorded, on the other hand, would seem to suggest that this method, which is the essential of cancellous grafting, has the very definite advantages of (1) providing the maximum number of osteophytes possible, and (2) providing a malleable

Fig. 6.

medium for the "lines of force" generated by carefully graduated active movements of the part when protected by accurate splinting. The results of these advantages are seen in the earlier return of function and the greater degree of symmetry obtained by this method than by the grafting of compact bone. Todd has shewn that no evil effects attend the removal of even large quantities of the iliac bone. In the case here recorded this question in view of the previous amputation hardly arose.

SUMMARY.

The suggestions put forward are:—

- (1) That the treatment of myelomata by curettage and autogenous bone grafting is worthy of a more extended trial, and, provided rigid

asepsis is observed, holds out the promise of good results.

(2) That cancellous grafts, as malleable bone forming media tend, in association with graduated movements and accurate splinting, to an earlier restoration of function and symmetry than do grafts of compact bone.

I am indebted to Lieutenant-Colonel S. R. Christophers, C.I.E., I.M.S., Director, and the Officers of the Central Research Institute, Kasauli, for the pathological examination and the microphotograph of the tumour material, and to the Editor, *Guy's Hospital Reports*, for permission to republish.

A PRELIMINARY NOTE ON THE PHARMACOLOGICAL ACTION OF SOME ORGANIC-ANTIMONY DERIVATIVES.*

By R. N. CHOPRA, M.A., M.D., B.Ch. (Cantab.),
MAJOR, I.M.S.,

Professor of Pharmacology, School of Tropical Medicine and Hygiene, Calcutta.

(From the Department of Pharmacology, Calcutta School of Tropical Medicine).

DURING the last decade a number of organic-antimony derivatives (aromatic) have been introduced for the treatment of certain tropical diseases of protozoal nature. The origin of these aromatic antimonials was due to the work of Michaelis and Reese whose investigations led to the preparation of triaryl-stibines. Later, Grignard's reaction gave rise to the preparation of triphenyl-stibamines. Most of the present development of the organic-antimony derivatives, however, is due to the work done by Chemische Fabrik Von Heyden who discovered the process of introducing into the aromatic nucleus the antimonial group through the agency of the diazo-

reaction. Great impetus was thus given to the synthesis of aromatic antimonial drugs and most of the antimony analogues of the aromatic arsenical drugs such as atoxyl, salvarsan, etc., were prepared. From aniline by diazo-synthesis it was quite easy to prepare phenylstibinic acid and then para-amino phenylstibinic acid (p-stibanilic acid) which is the antimony analogue of p-arsanilic acid. Its sodium salt, sodium-para-amino-phenylstibinate (or sodium p-stibanilate), is the antimony analogue of the arsenical compound known as atoxyl or arsamin (sodium p-arsanilate). This compound was later given the name of *stibamin* by Dr Brahmachari from its analogy to the corresponding salt of arsenic which is called *arsamin*. A derivative of this sodium acetyl-p-amino-phenyl stibinate was called *Stibacatin* which was one of the earlier members of the aromatic series to be used in therapeutics against leishmaniasis. This was put on the market by Messrs. Allen and Hanbury under the trade name of *Stibenyl*. This compound is soluble in water, is stable and does not irritate the tissues to the same extent as do some of the organic-antimony compounds. Unfortunately, however, it did not prove of any great therapeutic value in kala-azar in this country. The sodium salt of p-amino-phenyl stibinic acid, or sodium p-amino-phenyl stibinate (*Stibamin of Brahmachari*) is also a soluble compound which, though therapeutically active, is unfortunately not very stable. Its therapeutic application was, therefore, limited. The carbamide derivative of p-amino-phenyl stibinic acid was then prepared by Brahmachari by warming p-amino-phenyl stibinic acid suspension in water and urea, until the whole of the acid is almost dissolved; this is concentrated on a water-bath and the salt is precipitated by the addition of alcohol. The resultant substance was called *urea-stibamine* and is a pentavalent compound of antimony. Brahmachari believes this substance to be not a urea salt of stibanilic acid but a substituted urea. Henry has, however, criticised and doubted the constitutional formula given by Brahmachari.

The combination of urea with p-amino-phenyl stibinic acid renders this compound more stable and soluble (p-amino-phenyl stibinic acid is not soluble) and at the same time more efficacious therapeutically. It is a well-known fact that when quinine is combined with urea, its solubility and diffusibility is considerably increased and the resultant compound is able to penetrate better into the tissues; its local anaesthetic action is also much enhanced. The same probably happens in the case of *urea-stibamine*. Better penetrability of the compound probably accounts for the superior therapeutic results obtained by this drug as compared with the previous compounds. There are two brands of *urea-stibamine* on the market. Our chemist, Mr. N. R. Chatterjee analysed these samples of *urea-stibamine* and found them for all practical purposes to be the same. Dr. Napier has used both these brands

* Whilst this issue was in the press an announcement has been made that Dr. Brahmachari has obtained an injunction to restrain the Union Drug Company from using the name urea stibamine as a designation of the carbamide salt of p-amino-phenyl-stibinic acid.

The effect of this judgment is to give to Dr. U. N. Brahmachari the sole right to the use of the name urea-stibamine for the purposes of manufacture and sale of the drug.

We had hitherto been under the impression that the name urea-stibamine was a scientific description of a valuable drug which had been prepared by a medical scientist for the use of the whole world. According to the recent judgment it is only the process of manufacture which is common property, the name urea-stibamine is held to be a fancy trade designation, which Dr. Brahmachari alone is entitled to use.—EDITOR, I.M.G.

in the Carmichael Hospital for Tropical Diseases and the clinical results were equally good; I will show later in this paper that their pharmacological reactions in animals are almost identical.

Von Heyden a few years ago, introduced a compound, metachloro-para-acetyl-amino-phenyl-stibinate (Von Heyden 471) to which they gave the trade name of *Stibosan*, and later they introduced another compound, an amino salt of para-amino-phenyl-stibinic acid. Both these compounds have given very good results in kala-azar in Dr. Napier's hands. They are more efficacious than some of the earlier organic-antimony aromatic compounds such as *Stibenyl*, and are as good as *urea-stibamine*. A number of other organic-antimony compounds (aromatic) have been put on the market lately and some of them have been tried in the treatment of kala-azar with success. One of these compounds is p-amino-phenyl-stibinic acid urea-glucose, which has been prepared by the Union Drug Company, Limited, and they have given the compound the following formula $C_6H_4NH_2 \cdot CO \cdot NH \cdot C_6H_4 \cdot SbO(OH)(ONH_2)$. This compound has been given the trade name of '*Amino-stiburea*' and Napier has obtained good results with it in kala-azar. Yet another compound has been prepared to which the name of '*Novo-stiburea*' has been given, but its composition has not yet been disclosed. This compound is claimed by the makers to be quite stable; it can be dissolved in tap-water, its solution can be sterilized by boiling and it is said to have good keeping properties. If the compound is really stable and as effective therapeutically as *urea-stibamine* or *Stibosan* it will make a distinct

advance in the treatment of kala-azar. Most of the antimony compounds in use at present are unstable in the air even in a solid condition and in solution they change very rapidly.

These compounds are of great importance in the treatment of kala-azar and are being injected intravenously. No attempt has been made, so far as I am aware, to work out their pharmacological action. As these compounds are being used extensively in this country, I have undertaken to work out their pharmacological reactions in animals. In this paper the results of my observations have been summarised; but the detailed work with the graphs will be published later, in a more technical journal.

The Pharmacological Action of Antimony Compounds.—The pharmacological action of these compounds was investigated on cats. The animals weighed 1,800 to 2,500 grammes and were anaesthetized with urethane, a small amount of ether being given when necessary. The blood pressure was recorded by putting a cannula into the carotid artery and the volumes of the intestines, the spleen the kidney and the limb were recorded in the manner usual in pharmacological tests. The pulmonary pressure was recorded by the delicate method described by Jackson and Rapp. The drugs were injected into the femoral vein in doses ranging from 10 mgm. to 100 mgm. The 10 mgm. dose was, however, found to be too small to produce any effects, while with 100 mgm.s. the reaction was severe and often the animal succumbed. Doses of 50 mgm. gave good reactions and we used this quantity in most of our experiments. The results obtained are shewn in the following table:—

Table summarising the pharmacological action of Antimony Compounds.

	Sodium antimonyl tartrate.	"Urea-stibamine" Both brands.	"Stibosan" Von Heyden's 471.	"Amino-stiburea" Union Drug Co.	"Novo-stiburea" Union Drug Co.
1. Blood Pressure, Systemic.	Slight fall	Marked and lasting fall. Heart slow and irregular. Pressure regains its normal level.	Great fall, may go down to zero. Heart very irregular. Pressure slowly regains its normal level.	Slight fall of B. P.	Slight fall.
2. Blood Pressure, Pulmonary.	Fall followed by slight rise.	Marked and sustained rise.	Marked and persistent rise.	Marked rise.	Rise.
3. Cardiometer and Myoca-diograph results.	Marked momentary depression.	Slight but lasting depression.	Slight and persistent depression.	Slight and persistent depression.	Slight depression.
4. Isolated Heart (Mammalian).	Marked depression.	Momentary depression. Relaxation of ventricles.	Depression. Heart irregular.	Depression. Relaxation of ventricles.	Slight depression.
5. Respiration ..	No effect, sometimes slight stimulation.	Stops momentarily, then depressed. Amplitude decreased.	Stops longer, then restarts.	No effect.	Slight quickening.
6. Spleen volume	Increase.	Marked increase. Rhythmic movements.	Marked increase. Rhythmic movements.	Marked increase. Rhythmic movement.	Increase.
7. Intestinal volume.	Decrease	Decrease.	Decrease	Decrease	Decrease
8. Kidney volume	Decrease	Decrease	Decrease	Decrease	Decrease.
9. Limb volume ..	No effect	Slight decrease	Slight decrease	Slight decrease	Decrease.

Discussion of the Table.—A perusal of the table will show how the blood pressure, respiration, and different organs react to intravenous injections of antimony compounds. All the compounds with the exception of *Novo-stiburea* produced a fall in blood pressure immediately after injection, as will be seen from a glance at the horizontal column No. 1. The two brands of *urea-stibamine* we tested gave a marked depression amounting in some cases to 20 to 25 mm. of mercury. With *Stibosan* the fall of blood pressure was even more marked being as much as 50 mm. of mercury; in some cases the pressure went down to zero, the animal at the same time showed marked symptoms of collapse. The heart became slow and irregular but gradually recovered and the blood pressure came to the normal level. Dr. Napier informs me that occasionally he gets a case in which sensitisation develops, and suddenly after 5 or 6 injections, injection of the usual quantity of any of the pentavalent antimony compounds, produces marked collapse. I had a patient who had an injection of a small therapeutic dose of *Stibosan* for the first time and who showed all the signs of severe collapse.

All these substances have a depressant action on the heart and they relax the ventricles in the same way as do the cinchona alkaloids; this will be seen by a perusal of the horizontal columns Nos. 3 and 4. With regard to the effect on the pulmonary blood pressure recorded in horizontal column No. 2, there is a marked rise in pulmonary pressure with all the organic-antimony compounds which we have tested. It is worthy of note that arsenical compounds such as salvarsan also cause a marked rise of pulmonary pressure, and this is of interest in connection with the "nitritoid crises" which are produced by administration of this drug. It is quite likely that the symptoms which occur in patients after injections of antimonial compounds may be due to changes occurring in the pulmonary circulation. This point is under investigation. In horizontal column No. 5 will be seen the effect of intravenous injections of antimony compounds on the respiration. *Urea-stibamine* and *Stibosan* produce a more marked effect on the respiration than sodium antimony tartrate, *Amino-stiburea* and *Novo-stiburea*. With the two former drugs the respiration may cease for 10 to 30 seconds, but it is not permanently paralysed and quickly regains its normal amplitude.

The effect of antimony salts on the spleen is recorded in horizontal column No. 6. There is a well marked increase in size in all cases; with *urea-stibamine* and *Stibosan* this action is more marked than with tartar emetic. Is it possible that this increase in spleen volume has something to do with the therapeutic effect produced by these compounds in curing leishmaniasis? The spleen is a reservoir of parasites and the influx of blood charged with antimony into this organ might contribute towards the destruction of the parasites and cure of the disease. Horizontal

columns Nos. 7, 8 and 9 show the action on the intestine, kidney and limb volume.

I have much pleasure in acknowledging the help that I have received from Captain Premankur De and Mr. Nihar Ranjan Chatterjee in the course of this research.

SUMMARY AND CONCLUSION.

The action of a number of organic-antimony derivatives has been tested on cats. All these substances have a more or less depressing effect on the heart, circulation and respiration. The systemic blood pressure falls, whilst the pulmonary blood pressure rises. The volume of the spleen is markedly increased, while the volume of the intestine, kidney and limbs decreases.

AN ENTOMOLOGICAL EPISODE OF THE EAST AFRICAN CAMPAIGN.

By G. G. JOLLY, C.I.E., M.B., D.P.H., D.T.M. & H.,
MAJOR, I.M.S.,

Assistant Director of Public Health, Burma.

DURING the year 1915, I was stationed at a large post in East Africa in the crater-like depression of an isolated volcanic mountain. This mountain had been held for some months by the Germans, and when we occupied it, we found ourselves obliged for reasons of defence to place part of our troops upon the site of the old German camp. We had not been there for many days before we found that the site was heavily infected with jigger fleas, left doubtless by the African troops and porters of the German force.

Our men, mainly European and Indian troops who had little or no previous experience of the jigger, rapidly became infected to an alarming extent, and in a few weeks' time nearly half our garrison was unfit to march. Everything that could be thought of was done. All troops wore boots and socks and were warned not to put their naked feet to the ground. Tent flaps were raised during the day to allow sunlight to beat upon the floor. Tent sites were frequently changed, and a weekly inspection of the men's feet was instituted and all jiggers removed and killed. Still the disease continued. Raised beds constructed from brushwood were built inside the tents and the floors leaped to reduce dust. Kerosine oil emulsion was sprayed on the floors of tents and huts, and the men's socks were treated with the same solution. Facilities were

provided for the men to have daily baths. Inspection of feet was increased to twice a week; still there was little appreciable reduction, and the number of men attending hospital for dressing of septic jigger sores severely taxed our medical resources. Matters became so serious that it was feared that evacuation of the camp would have to be urged on medical grounds.

At this juncture I made the somewhat novel proposal that we should completely reverse our policy, stop all our kerosine oiling, etc., and either order or at least encourage all men when in camp to go about barefoot. I further proposed to inspect the feet of each man in the camp every day.

As can readily be imagined, the proposal met with a good deal of opposition, but with the moral support of an I. M. S. colleague and having regard to the failure of our previous methods, I succeeded in obtaining permission to give my proposal a trial. All officers were asked to advise their men to go barefoot in camp as far as possible, and I made arrangements in my ambulance for daily foot inspection and jigger removal. About sixty African stretcher bearers, experts in the detection and removal of jiggers, were utilised for this purpose, and each was provided with a small tin for removed jiggers, which were collected in bottles containing perchloride of mercury and counted. Medical orderlies armed with bottles of tincture of iodine painted the small wounds caused by removal of the jiggers, and applied dressings to the more serious cases.

The number of jiggers caught and destroyed in the first few days was rather alarming to their human hosts. In spite of all precautions I myself had eleven jiggers in my foot, and removed at one time as many as sixty from the feet of an Indian sepoy.

By the end of a week, however, there was a noticeable reduction in jigger infection, which was much more marked by the end of a fortnight; and in a month's time from the institution of the system the jigger scourge had practically ceased to trouble us, and the number of jiggers removed daily per 100 men had dwindled from 315 to 5.

The result in spite of the dislocation of duties caused by the daily inspection wholly justified the measures adopted.

At the end of a month I was obliged, for reasons beyond my control, to reduce the inspection of feet from daily to twice weekly, but in spite of this the number of jiggers was kept down to such an extent that they ceased to be a further source of danger.

It seems probable that had I been able to keep up the daily inspection of feet and removal of jiggers for another month, I would have trapped and destroyed all the jiggers in the camp.

The success of this experiment depended of course upon the fact that the jigger flea can only breed in the body of its host, and that our daily inspection prevented this by detection and

removal of the female jigger before it had time to develop its eggs. The victims of the parasites themselves became the trap which lured the jigger to its destruction. In this case we are assisted by the comparative absence of suitable hosts other than man, and by the isolated position of the post, which prevented repeated reinfection.

A NOTE ON THE USE OF EMETINE INTRAVENOUSLY.

By V. N. DEUSKAR, L.C.P. & S., I.M.D.,

Haddo, Port Blair.

WITH much interest I have read Dr. Vasavada's letter published on page 478 of the *Indian Medical Gazette* for September 1924, and another one by Major Porter, D.S.O., R.A.M.C. (retd.), on page 589 of the November number of the same year; and I do not think it is too late to support their views on the use of intravenous administration of emetine on the strength of the following experience.

From June to December, 1925, I was lucky enough to have an opportunity of treating as many as 70 cases of amoebiasis in the dysentery ward of the Haddo Hospital, including 6 relapses, with a case mortality of roughly 12½ per cent.

The routine method adopted for the treatment of these cases was to give them a one-grain dose of emetine intravenously for nine consecutive days, followed by an interval usually of six days during which time only a morning saline aperient was given; after this they were again given intravenously another course of six injections similar to the above on six consecutive days. Deek's intensive bismuth medication was combined with emetine as a rule and consisted in the administration orally, of two drachms three times a day of either the carbonate or the subnitrate. Later, however, when the stock of bismuth ran short in the hospital, it was either replaced by sodium bicarbonate given in 30-grain doses, three times a day, or the treatment carried on with emetine alone.

Thus it will be seen that each patient at the end of the treatment had received a total of 15 grains of emetine and altogether well over 1,000 injections were required for the treatment of the whole series.

During the course of the treatment, the patients were carefully observed and after completion of the course, they were usually kept in the hospital for several days before being finally discharged. On being discharged from the hospital, they usually joined what is called the "post-dysenteric gang," when they did light labour, stayed within the hospital premises and attended the hospital once daily. As a rule no patient is sent back to full labour unless he has been in the post-dysenteric gang for a period of at least one month; and during this time of their stay a weekly examination of the stools is carried out.

It may not be out of place to mention here that in each case the diagnosis was accurately established by the microscope and nothing short of the presence of actively motile *Entamœba histolytica* was accepted as proof positive of the condition before the treatment was commenced.

On the strength of the experience gained, it can safely be said that the method of treatment, besides being altogether painless, is simple and safe and is devoid of the dangers it is commonly supposed to involve. No reaction of any sort either immediate or remote was noticed; and in not a single case was there any reactionary pyrexia noted. On one occasion, however, three patients injected at the same time, developed a rigor soon after the injection; but this I am inclined to attribute to some fault in the rain water used to dissolve the emetine rather than to anything else, for the reason that these patients had received their previous injections all right and showed no such symptoms on receiving their subsequent injections. On the whole the results obtained were fairly uniform. Only two of the patients complained of any giddiness or lethargy and none of them had anything like emetine diarrhœa or what is called post-emetine debility. The two cases referred to, complained of weakness and giddiness and developed tachycardia soon after 3 grains of emetine was given to them, but this could be easily accounted for by the fact that they had undergone full courses of emetine only about a fortnight prior to their admission to this hospital.

With reference to the nature of cases treated, it is important to note that some of the cases who received the above treatment were in an advanced state of debility and anæmia consequent upon the co-existence of various other infections. Some cases of the series had as low a weight as 83 lbs., and as low a hæmoglobin value as 40 per cent. Amongst the lot, 12 patients had associated malaria and 6 had a co-existing infection with ankylostomiasis. There were two who had malarial cachexia with their spleens reaching to below the umbilicus and across the median line; and one of these had a febrile attack from 27th August, 1925, to 11th September, 1925, and showed malignant tertian rings in the blood as late as the 10th September, 1925, with a hæmic murmur and a hæmoglobin value of 45 per cent. There were again two others who had ankylostomiasis, bronchitis and at the same time a mixed infection of benign and malignant tertian malaria besides having amœbiasis; and there was one case where sprue co-existed with the attendant emaciation, debility and hæmic murmur.

In spite of the nature of cases being such as has been described, tolerance to the form of treatment prescribed was fairly satisfactory and it may be justly concluded that there is no reason why such a method of treatment should not be extended to patients in private practice, if rest in bed whilst under treatment can be rigidly enforced.

In private practice, however, a close watch of the patient is often not possible and at the same time a maximum of benefit is desired with a minimum of risk; and it is here only that the need for adopting the safest course possible cannot be too strongly emphasised. Under such circumstances the ideal treatment to be recommended would be the one advocated by Majors Acton and Knowles in the July 1924 number of the *Indian Medical Gazette*, where the total emetine received by the patient does not exceed a maximum of 12 grains. With this dosage, emetine administered intravenously would be as safe a procedure as when given by any other method.

Whether the therapeutic efficiency of emetine is increased by its administration intravenously is a question that cannot be answered at present as it does not lie within the scope of the present paper. Before answering this it will have to be ascertained (1) whether with this treatment negative results of the stool examinations are more quickly obtained than otherwise; (2) whether the subsequent effect of emetine is of a more lasting nature; and should the answer to this be in the affirmative then, (3) to what extent is the tendency to relapses cut short? All these questions, it is hoped, will be dealt with at a later date on obtaining a second microscope exclusively for the use of the dysentery ward.

With regard to the treatment of chronic cases it is feared that the value of emetine is not improved by this method and one should not be surprised if the results prove as disappointing as with other methods of administration as will be seen from the tabulated details of the six relapses. Considering again the massive thickening and fibrosis of the gut found at post-mortem examinations conducted on such cases one can only feel pessimistic as regards the prospects of cure of such pathological conditions under any drug treatment.

Details of Relapses.

No.	Date of discharge after 15 grains of emetine intravenously.	Date of readmission with relapse when motile <i>E. histolytica</i> was again recovered.	No. of days after which relapse occurred.
1	19-6-1925	3-11-1925	136
2	20-7-1925	5-9-1925	46
3	9-8-1925	3-12-1925	115
4	8-9-1925	28-12-1925	110
5	19-9-1925	8-12-1925	79
6	12-12-1925	6-2-1926	55

Lastly, I am much indebted to Dr. A. Bayley-de Castro, Junior Medical Officer, Haddo, not only for letting me have free scope for work but also for the personal interest he took in the dysentery patients.

SUMMARY.

(1) From June to December, 1925, 70 cases of amœbiasis, including six relapses, were treated

in the dysentery ward of the Haddo Hospital with a case mortality of about $12\frac{1}{2}$ per cent.

(2) Emetine intravenously was made use of combined as far as possible with Deek's intensive bismuth treatment; altogether over 1,000 injections were given.

(3) Nine injections, each of one grain, on 9 consecutive days were given, followed by an interval usually of 6 days; after which another 6 injections were similarly given, so that each patient at the end of the course received a total of 15 grains of emetine.

(4) The series included cases with as low a weight as 83 lbs., and as low a hæmoglobin value as 40 per cent. It also included cases of advanced debility and anæmia consequent upon the co-existence of various infections such as acute malaria, malarial cachexia, bronchitis, ankylostomiasis and sprue.

(5) The tolerance to the form of treatment prescribed, however, was fairly satisfactory and no toxic symptoms due to emetine were recorded.

(6) The use of emetine intravenously, besides being painless, was found safe and simple and appears to be practically free from the dangers it is commonly supposed to involve.

(7) If rest in bed could be rigidly enforced during treatment (which is equally necessary when emetine is given by any other method) it would be quite safe to extend this method of treatment to patients in private practice, provided that the total emetine so given does not exceed a maximum of 12 grains.

(8) The question whether emetine on intravenous administration gives better therapeutic results remains undetermined, as no such attempts could be made for want of proper means and facilities.

(9) From the extensive thickening and the massive fibrosis of the gut seen at post-mortem examination on the fatal cases and in view of the fact that relapses occurred within a period varying from 46 to 136 days, it appears that so far as the treatment of chronic cases is concerned the results under this treatment are as disappointing as with any other method of administering emetine.

CHOLERA AND RIVER WATERS.

AN EPIDEMIOLOGICAL SUGGESTION.

By G. G. JOLLY, C.I.E., M.B., D.P.H., D.T.M. & H.,
MAJOR, I.M.S.,

Assistant Director of Public Health, Burma.

Two extremely interesting and important papers have appeared in the *Indian Journal of Medical Research*, by Ross and Bagchi, on "The seasonal variation in the reaction and hardness of river water in India." The authors have demonstrated the occurrence of a change in the reaction of Ganges river water from alkaline to acid beginning about April, before the onset of the rains, and a swing back from acid to alkaline

in October or later. They have shown that the acidity is due to the presence of free CO_2 , liberated from the calcium bicarbonate present in the water, which is replaced by calcium nitrate. These observations have an important bearing on the question of turbidity of rivers and the natural and artificial purification of these waters.

The basin of the lower Ganges is generally recognised as the endemic home of cholera, and it is well known that cholera has a tendency to become endemic in the basins of great rivers. Cholera in India is a definitely seasonal disease. On this point Sir Leonard Rogers remarks: "In Lower Bengal and Calcutta the disease is present throughout the year, but has a very definite maximum season in the dry months of March to June when the ground water level is at its lowest point, and the water-supply most deficient and foul, and an equally marked minimum in the rainy season with a high water level and very thorough flushing out of all water-supplies." Referring to cholera in the basin of the Brahmaputra in Eastern Bengal and Assam, the Sanitary Commissioner with the Government of India states in his Annual Report for the year 1909: "The curve of monthly deaths showed a double rise, the first during March, April and May, the second during October to December. These epidemic rises indicate for this province the usual seasonal incidence of the disease, which is thought to depend upon the rise and fall of the great rivers." In the same report for the year 1918, referring to India in general, the statement appears: "Cholera is markedly seasonal and there are generally two waves each year. The major wave is between April and July and the second or minor wave is in the autumn, in October."

It will be noted that these waves of cholera incidence coincide more or less closely with the change-over in the reaction of Ganges water discovered by Ross and Bagchi, the neutral points occurring simultaneously with the two cholera waves.

These facts suggest the possibility that there may be some connection between the two phenomena. We know that pure water is not a good culture medium for cholera vibrios; we also know that the organism is sensitive to acid, but can grow readily in a medium which is so alkaline as to inhibit the growth of other organisms. Stitt puts the pH limits for growth of *Vibrio cholerae* as 6.4 to 7.9 and the optimum limits as 7.0 to 7.4, and it appears reasonable to assume that the organism will stand a better chance of surviving and multiplying in Ganges water when the pH is between these limits. Writing on "The influence of pH upon bacterial metabolism," Mansfield Clark states: "The reaction of the medium even within the zone of optimal bacterial growth is found to influence either the rate, or the relative rate of specific types of metabolism." In Ross and Bagchi's observations the neutrality points were estimated by means of neutral re-

and the useful range for that indicator is a pH of 6.8 to 8. It is evident, therefore, that Ganges water will have a pH favourable to the growth of cholera vibrios at or about Ross and Bagchi's neutral points, which as already mentioned, coincide more or less closely with the two cholera waves. Ganges water must be subject to repeated infections throughout the year, but it is possible that the infection dies out rapidly at times when the reaction of the water is either too acid or too alkaline for the organism to multiply rapidly, and when the temperature also is unfavourable.

I suggest that this interesting relationship between the reaction of Ganges river water and the two rises in cholera in each year may be more than a coincidence, and that the change which takes place in the reaction may prove to be a factor of importance in the epidemiology of cholera.

EAR, NOSE AND THROAT DISEASES AMONG CALCUTTA UNIVERSITY STUDENTS.

By J. K. DATTA, M.B. (Cal.), F.R.C.S. (Edin.),
 M.R.C.S. (Eng.), L.R.C.P. (Lond.),

Oto-rhino-laryngologist, Carmichael Medical College Hospitals; Surgeon, Sambhu Nath Pandit Hospital, Calcutta.

THE Calcutta University Student Welfare Committee have very kindly asked for my views in the matter of medical examination of college students with reference to ear, nose and throat diseases. As I consider the subject to be of great importance not only from the point of view of the college students but also from that of the community in general, and hence deserving of much more attention than it generally gets, I thought I might write something about the significance of these diseases in the *Indian Medical Gazette*.

The committee have been conducting the medical examination of the Calcutta college students since March 1920, with a view to ascertaining the general condition of their health. These examinations have revealed a most appalling state of affairs, which demands most urgent and immediate attention. It has been found out that 71 per cent. of the students suffer from some sort of physical defect or other. Most of these are preventable, if attended to at a sufficiently early stage.

The importance of these health examinations cannot be over-estimated and this effort is certainly a move in the right direction. But the usefulness of these examinations would have been greatly enhanced if instituted at a much earlier state. What I mean is that a comprehensive system of *school* medical examination should be adopted in addition to these college examinations, as is done in England and other European countries. The reason for this is obvious. Many of the ailments from which our college students are suffering date back to their childhood or school days, and it is then that the disability, if detected, being at its very onset, would have the best chance of being easily corrected. This is applicable very particularly to ear, nose and throat diseases.

Unfortunately there is no branch of surgery which is so much neglected in this country as that of ear, nose and throat diseases. Every day in the hospital clinics are seen numerous cases where an acute inflammatory condition of the middle ear has been allowed to progress until a state of chronic suppuration, with all its attendant sequelæ, has resulted. What an enormous number of students—both in the schools and in the colleges—there are who have got diseased tonsils, adenoids and enlarged glands in the neck, with broken-down constitutions and flat, deformed chests. The pity of it is that the patients do not seem to realise the seriousness of these diseases at their early stage and even when they are fairly advanced they do not generally undergo proper treatment. This deplorable state of affairs is due mainly to ignorance and apathy of the general public and to some extent, if I may be allowed to say so to indifference on the part of the attending physicians.

Over 70 per cent. of all ear diseases are middle ear diseases and these may be catarrhal or suppurative in nature. These, if long-continued and not properly treated, will end in deafness. Infectious diseases, e.g., measles, influenza, whooping-cough, small-pox, typhoid fever, scarlet fever, etc., are responsible for the majority of the worst types of suppurative middle ear disease and it is at their beginning that so much can be done to prevent a progressive and chronic disease with consequent deafness. It goes without saying that once deafness has set in and has been moderately severe, it renders a man incapable of being useful in any sphere of life. There is the further handicap that none of the prominent life insurance companies will accept an applicant with chronic or intermittent otorrhœa and here we are brought face to face with the business man's view of the disease. Hence it is very important not to neglect these ear diseases at their early stage.

What then are the early symptoms of these troubles? I will give here, in the briefest possible manner, a few typical symptoms in illustration. The patient will say that all on a sudden

one night he felt a severe pain in his ear and since then it has been "stopped" and he cannot hear distinctly with that ear. Along with this there may be a slight rise of temperature and a general feeling of illness. From this short history we can guess that the patient is suffering from acute otitis media. Again a father will come with his child, with the story that the boy has of late been listless and does not respond to questions unless these are repeated twice or thrice. Another patient will complain that he feels "very heavy" in his ears and is being disturbed with all sorts of buzzing noises in them. Here we have before us cases of catarrhal otitis media with the beginning of deafness. Naturally we are asked if there is anything wrong in their ears. We examine the ears but our examination must not stop there. The ear is never thoroughly examined until we have examined the nose and throat. It is not recognised by the public, and not much importance is placed by the general practitioner and those not practising the speciality, on the fact that an aural condition may have been—has been, indeed, in a large proportion of cases—caused by some abnormal or diseased condition of the nose or throat: the recognition of a nasal or nasopharyngeal abnormality is often the first step in the amelioration or cure of aural disease. In this connection adenoids may be mentioned as an instance, not only in children but also in adults: their detection at any age is a gain.

Here I may describe the two simplest tests which I consider most suitable for testing the hearing of students. These are the voice test and the watch test.

The voice test.—The practical test of hearing is the ability to hear ordinary conversation, but as the pitch and loudness of the spoken voice vary considerably in different persons and often in the same person at different times, the whispered voice, being more uniform, is more reliable as a test of hearing, provided the deafness is not so intense that the whisper is heard with difficulty or not at all.

Method.—The patient stands at one end of a quiet room with the ear to be tested towards the examiner, the other ear being stopped with the index finger. The examiner begins the test from without the range of the patient's hearing, say at a distance of about thirty feet, and gradually comes nearer until the patient repeats correctly what is spoken or whispered to him, and the distance so found is entered on the record. The spoken or the whispered voice is used according to the degree of deafness, and the record should state which method of speech is used.

If the ordinary conversational voice can be heard correctly at about twenty or thirty feet, the hearing for the voice may be considered normal. Any distance less than that indicates defect, as a rule. The whisper may be heard in a quiet room by a normal ear at about twenty feet.

The watch test.—This test is not as good as the previous one; watch-ticks are not standardised, and the hearing for the watch is no indication whatever of the hearing for conversation. Its advantage is that it can be carried on with comparative ease and hence is universally applicable.

Hold the watch beyond the point at which it is normally audible, and gradually bring it near the patient's ear. Note the distance of the watch from the ear when the patient first hears the tick. During the test the other ear must be stopped with the finger and the eyes must be closed.

The nasal affection which may cause harm to the patient may be obstructive or infective, though in many cases both are commonly present together. There may be deviation of the nasal septum, hypertrophy of the turbinal bones, polypi, or suppuration in the nasal accessory sinuses. Troubles in the middle ear, such as deafness or otorrhœa, may arise from any of these. These nasal conditions may also be factors in the causation of various local and remote symptoms. Amongst the local manifestations may be mentioned stuffiness in the nose, inability to breathe through one or the other nostril or through both, repeated attacks of coryza, offensive breath, headache, pain varying in situation and degree, purulent nasal discharge, etc. The significance of a nasal condition in the causation of headache must be kept in mind and in every such case the nose should be examined as a routine measure, which, if done, will obviate many unnecessary troubles. Here I may mention the case of a patient, a young adult, who came to me in May, 1925, complaining of frontal headache of about a year's duration. He had been under various treatments but without any improvement. Glasses had been ordered but his headache remained as before. He used to suffer from colds in the nose. On examining his nasal passages I found the left middle turbinal bone much hypertrophied. Transillumination showed the frontal sinuses and maxillary antra clear. I performed turbinectomy of the enlarged bone and ever since then he has been free from the headache. Here the turbinal bone was interfering with the proper drainage of the frontal sinus leading to increased intra-sinus pressure and consequent headache.

Regarding the remoter manifestations, gastric, respiratory, ocular, cardiac, muscular or arthritic symptoms may be complained of, and amongst the nasal affections the infected accessory sinuses are the most important factors in their causation. As illustrating these, I shall describe here the history of two patients who have been under my care.

One patient, an adult male, suffered from dyspepsia for a long time. Various methods of treatment were adopted but without any improvement. He suffered from chronic catarrh in the nose. Nothing abnormal could be found in the pharynx or the post-nasal space but on examining

the nasal passages I found yellowish-white, tenacious, pus-like discharge sticking on to the left middle turbinal bone which was also slightly enlarged and œdematous. The maxillary antra and the frontal sinuses were clear on transillumination. I thought the case to be one of ethmoidal suppuration. The hypertrophied middle turbinal was excised and the ethmoidal cells were exenterated and the cavities were disinfected with collosol argentum liquidum. The removal of the septic focus in the nose led to improvement in appetite and general health and the patient felt relief from his stomach disorder.

The second case is of interest as showing how an infection in an accessory sinus can cause evening rises of temperature, general debility, anæmia, cough and all the symptoms suggestive of pulmonary tuberculosis. No focus in the lung could be detected, still the patient, an adult female, suffered from the above symptoms. There were a few granules on the posterior wall of the pharynx but excepting these no other abnormality could be found in the pharynx and the post-nasal space. The larynx was quite normal. On examining the nasal cavities I found pus sticking on the medial surface of the right inferior turbinal bone. Transillumination revealed a dark maxillary antrum on the right side. Proof puncture and syringing brought out purulent fluid. Obviously the symptoms were the result of septic absorption from a suppurated maxillary antrum. Nasal antrostomy being refused, the right maxillary antrum was washed and disinfected with collosol argentum liquidum. The patient gradually showed signs of recovery. The evening rises of temperature dropped, cough disappeared and she put on flesh and was once again a cheerful soul.

I cite these two cases only to show the significance of a focal infection in the nasal accessory sinuses, and this should never be forgotten even when the symptoms complained of by the patient refer to distant organs. And I cannot leave this point without mentioning, nay emphasising, the relationship of a diseased sinus to defective vision. In this connection the sphenoidal sinus and the posterior ethmoidal cells must be borne in mind and disease in these is one of the most common causes of retrobulbar neuritis with defect or loss in sight. And this is easily explained when we think of the anatomical relationship between the optic nerve and the sphenoidal sinus and posterior ethmoidal cells, only a thin bony partition separating the structures, whilst the optic nerve is very sensitive to toxins. Defective vision is quite common amongst the students and in its investigation the question of the accessory sinuses should never be overlooked: here is an opportunity for the ophthalmologist and the rhinologist to work hand in hand for the common good.

Amongst the throat and naso-pharyngeal conditions diseased tonsils and adenoids are the most potent factors in causing mischief to the

person, suffering from these, in various ways. The tonsil is a collection of lymphatic tissues situated between the two pillars of the throat. In young children the tonsils are at the height of their physiological activity and they are in some measure a protection against the invasion of micro-organisms. A healthy tonsil readily absorbs the pathogenic germs and has the power to destroy them.

The tonsils are very commonly enlarged and this enlargement is due to chronic infection and is often associated with adenoid vegetations in the post-nasal space. From their very bulk the tonsils sometimes cause difficulty in swallowing and respiration. Enlarged tonsils are septic tonsils and so these patients, both children and adults, are subject to repeated attacks of tonsillitis, quinsy and pharyngitis; to laryngitis, bronchitis and asthma; to acute rheumatic fever with its bad after-effects, diseases of the heart and chorea; sometimes to acute nephritis; and even, it is said, to appendicitis and other forms of gastro-intestinal disorders. Patients with chronic tonsillitis sometimes suffer from chronic rheumatism with repeated attacks of pain in the joints and osteo-arthritis, and I have got records of two cases who were permanently cured of their pains in the joints after I had removed their diseased tonsils. The strongest indictment against the tonsil is that it is the portal of infection for tubercle bacilli, which, passing through, often leads to enlargement of the lymphatic glands in the neck and tuberculosis in them, and at times to tuberculosis in the lungs. Conditions of anæmia combined with indigestion from toxæmia, often associated with evening rises of temperature and general debility are not uncommonly seen. Various eye troubles, e.g., retro-ocular neuritis and retinitis, phlyctenular conjunctivitis, may have their ultimate source of origin in diseased tonsils, which are also the factors in the causation of middle ear disease, catarrhal or suppurative, with deafness. All these diseases can be prevented or cured if suitable remedial measures are taken at the proper time. Medical treatment may do good at the beginning, but once the tonsils are chronically enlarged nothing short of surgical interference can effect any cure or improvement: the diseased tonsils must be removed *in toto*.

The public very often ask, if the tonsils are useful organs and have some protective value, why should it be prudent to remove them. The argument is that the tonsils may be compared to forts around a city, useful at first but not when in occupation of the enemy, when, therefore, they must be destroyed. The tonsils are useful when they are healthy, but once they are diseased, they are not only not harmless and functionless but are a definite menace to health and hence must be removed.

Before advising their removal the tonsils should be properly examined. Generally these organs are examined rather carelessly and hurriedly. Simply illuminating the pharynx and

putting a tongue depressor in position will not show the tonsil fully and properly. It must be borne in mind that its surface looks towards the middle line. Much—it may be most, in some cases it will be all—of the gland is hidden behind the anterior pillar of the fauces, and at the most only its anterior part is properly seen. The correct way to examine the tonsil is to draw back the anterior pillar and so to turn the tonsil towards the observer. This can be done by making the patient “gag”—during this act the muscle in the posterior pillar contracts and lifts up the tonsil out of its bed and at the same time rotates it forwards, making the gland fully visible. Or the anterior pillar can be hooked outwards by the tip of the tongue depressor and thus the face of the tonsil can be turned forwards. Whilst this is being done pressure can be made on the gland to see the condition of the crypts and the supra-tonsillar fossa: if there is any pus in these, it will be made evident. Many diseased tonsils, especially in adults, are overlooked, simply because these little procedures are not employed.

Adenoids.—Normally there is present at birth a variable quantity of lymphoid tissue in the roof and posterior walls of the naso-pharynx. By the term “adenoids” is meant a chronic enlargement of these lymphoid tissues. The incidence of adenoids is universal and is quite common in this part of our country. Though not exactly hereditary, it is in many instances a familial disease, three or four members of a family are often found suffering from this malady. Chronic or repeated attacks of nasal catarrh are the principal factor in their causation; the infectious fevers, particularly measles, whooping cough, diphtheria and scarlet fever, are also a frequent cause of this hypertrophy.

These hypertrophied adenoid growths gradually disappear or shrink by the formation of fibrous tissue in their substance. This process, however, does not depend on the age of the patient, and is not one that must commence at or about the age of puberty, but may occur at any age: it may even be more evident in the very young child than in the adult; sometimes the adenoid growths may remain up to old age, though in many cases these atrophy and disappear by the age of twenty or thereabouts. Thus, it follows that we cannot say in any particular case that a growth may be left to disappear by itself. Because a patient is approaching puberty or adult life it does not follow that the adenoid hypertrophy will in a short time cease to exist.

These facts ought to be given a wide circulation among the medical profession because physicians too often advise their patients to “wait for puberty” as the adenoids will “shrink” by that time. This adenoid tissue is always subject to infection and the patient suffers from repeated attacks of naso-pharyngeal catarrh. So while waiting, this inflammation is ever progressing, and may and actually does, in the

majority of the cases, spread into the Eustachian tubes and middle ear, causing symptoms which may linger on throughout the whole life of the patient. So even if the adenoids shrink, their bad effects do not disappear along with them but remain behind as a permanent legacy. Need we then wait for the adenoids to shrink when we know that that event is so uncertain, and when their presence is associated with so much risks? “Waiting for adenoids to shrink is always a foolish and dangerous thing.”

The symptoms of adenoids are many and various and are secondary to (1) the liability of these growths to infection or catarrh; (2) the extension of the inflammation to neighbouring organs; (3) the obstruction they present to nasal respiration; and (4) the reflex processes attributed to irritation and lowered vitality. These patients are always suffering from “colds” and easily get “catarrh of the nose.” Their breath is often foetid and their taste and smell are often impaired. The terribly common catarrhal and suppurative affections of the middle ear, leading to deafness if long-continued and neglected, are in an overwhelming majority of cases the result of adenoids. The presence of a chain of slightly enlarged lymphatic glands along the posterior border of the sternomastoid muscles is an almost constant sign of a mild infection of the pharyngeal tonsil. Sometimes these glands attain quite a large size and are often associated with slight rises in the evening temperature. Tuberculosis of the glands is usually due to the passage of the tubercle bacilli through these portals, i.e., the adenoids, and tubercle bacilli may enter the whole system after primarily infecting the lymphoid tissue. Slight bleeding from the nose (epistaxis) is quite a common symptom and is due to congestion of the naso-pharyngeal adenoid tissue. Owing to the same cause bleeding may occur into the throat and if to this, slight evening rises of temperature, cough and general malnutrition are added, the clinical picture of tuberculosis is very much suggested. Looking back into my case notes I can find the records of several cases in young adults who have been permanently cured of their symptoms by the removal of adenoids.

The inflammation from the naso-pharynx may spread to the larynx causing laryngitis, spasm of the glottis and hoarseness; to the trachea and bronchi causing bronchitis and possibly asthma, and leading along with the nasal obstruction to round shoulders, flat chest and depressed lower costal cartilages. Adenoid subjects are mouth-breathers and they snore at night. Restlessness during the night is a prominent symptom. Persistent nasal obstruction during the period of growth leads to some deformities in the jaws and face, the person having a dull, vacant and expressionless face or what is known as “adenoid facies” or “rabbit-shaped face.” They suffer from chronic anæmia and malnutrition and their bodily development is poor. Their mental faculties are often much impaired. They are

inattentive, possibly because they suffer more or less from deafness, and they cannot concentrate their attention on anything for a long time. Defective speech is a symptom of considerable diagnostic and economic significance. The voice is muffled and articulation is thick and imperfect.

How to detect the adenoids? This can easily be done if the attending surgeon uses his special senses. On inspection he will notice the open mouth, thick, everted lower lip, and dull, vacant and expressionless face. If the case has gone on for years deformed chest may also be evident. The post-nasal mirror will show the dark-red growths in the naso-pharynx. By the sense of touch the surgeon will feel with his finger the soft, velvety masses occupying the roof and posterior wall—and it may be, also the upper part of the lateral wall of the naso-pharynx. The olfactory senses will appreciate the foetid odour of the patient's breath while the auditory sense will detect, in some cases at least, the peculiar muffled character of the voice.

What is the treatment of these adenoid growths? "There is but one treatment worthy of the name, and that is the surgical removal of the growth (i.e., adenoids). Astringent applications have been and are still advocated by some writers, but in my opinion their use is but a means to postpone the day when their removal must take place. I can conceive how a congestion and inflammation of the lymphoid masses might be relieved and greatly improved by the local use of alkaline and astringent washes, but when true hypertrophy has occurred the curette offers the best means of treatment."

The improvement in the mental development after operation is often marvellous, provided the operation is done sufficiently early in life, but if this is delayed until the individual has attained full growth, the mind will rarely develop so well as it would have done had the operation been performed at an earlier period. The general health rarely improves and the person is always ailing so long as adenoids remain. If, however, these are removed, the general toxæmia disappears, the blood becomes oxygenated and red and all the vital energies are quickened and increased. The dull "adenoid facies" improves somewhat with advancing years, though it often remains as a permanent disfigurement. In fine, the early removal of adenoids often prevents serious aural diseases, improves the general health, and beautifies the face.

Persons with diseased tonsils and adenoids are very subject to the infectious diseases, e.g., measles, influenza, diphtheria, scarlet fever, etc. The public may think that the removal of these lymphatic tissues, which have some protective functions, will render the individuals more susceptible to infections but experience shows that this is not the case. The resistance to infections possessed by the individual in whom diseased tonsils and adenoids have been removed is certainly not lowered but is rather increased by the removal of the septic focus. Investigations in the

London County Council Schools as to the relation of tonsils and adenoids to the incidence of scarlet fever and other infectious diseases were made some years ago, and it was found that (1) cases of enlarged tonsils and adenoids provided the largest number of cases of infectious diseases; (2) persons who never had enlarged tonsils and adenoids came next; (3) the least frequent were those who had had tonsils and adenoids removed. The conclusion seemed to be that the frequency was decreased by removal.

I have attempted to write, briefly, about the significance of the commonest of the ear, nose and throat diseases; enlarged tonsils and adenoids stand most prominent amongst these. The treatment of these latter is entirely surgical. The public in India have a peculiar dread of surgery and cannot tolerate the idea of their children being subjected to a surgical operation and instead stuff them with syrup ferri iodide and cod-liver oil and use every known variety of gargle and paint, though deriving no benefit from these. I must confess I cannot sympathise with this attitude, fine in itself but cruel in its results; in my experience hard heads contain more real kindness than soft hearts. It is generally forgotten that the tonsils and adenoids are at the very gates through which all sorts of disease germs enter the body. Just as one's treasures are never safe unless the gates of the house are well secured, so unless the throat and nose are perfectly healthy and well-toned, one never knows when disease may not enter the body stealthily and rob the patient of health, the greatest of all treasures. Before making a decision one may naturally ask if there are any risks attending such an operation. Complications, such as septic infection of the wounds leading to troubles in the ear and hæmorrhage occur only very rarely indeed, and with proper precautionary measures the chances of their occurrence can be reduced almost to nil. If I may be permitted to speak from my personal experience, I may say that during the last nine years that I have been doing ear, nose and throat work—both in England and in India—I have operated on several hundreds of cases of enlarged tonsils and adenoids, and not one case even has suffered from any septic complication and I had to interfere in only one patient for slight bleeding which occurred on the fourth day after the operation and stopped on the application of tincture perchloride of iron. And I have not had a single fatality. This will show how baseless are the fears entertained against these operations.

The Calcutta University Students' Welfare Scheme is an important institution and it can do really useful work. The students are the young "hopefuls" of the nation and it is a national problem to investigate their health, to find out their defects and disabilities and to correct these by suitable remedial measures. As has been mentioned before, ear, nose and throat diseases are very much neglected in our country and these are allowed to progress till in most cases it

becomes too late for any successful treatment. The responsibility for this state of affairs rests both with the public and the medical men. The ignorance of the public with regard to the health of their children must be removed and with a view to educate them in this matter propaganda work, in the form of lantern lectures, etc., showing the signs and effects of these diseases, may be arranged. A system of *school* medical examination should be adopted. Every boy should be examined once on admission into the school, say, at the age of six, and secondly, when the student is twelve years old, and after that according as the boy's health necessitates him to be medically examined. There should be a service of school medical officers to undertake this work and to look after the health of the students generally. When a student is found suffering from any disability he should be referred to his family physician or to the specialist for necessary treatment. The care that is taken of the children in the schools is impressed upon the parents and they learn to regard a high standard of health as of value. In order to equip the general medical practitioner for this special work the following suggestions may be recommended:—(a) compulsory training with examination of the medical student in ear, nose and throat diseases; (b) establishment of a lectureship in the subject in the medical colleges; (c) appointment of an ear, nose and throat surgeon on the visiting staff of all teaching hospitals. In addition to an out-patient department, there should be a few special beds in every such hospital for these diseases, as there are for ophthalmic and children's diseases, so that medical students may get instruction in every variety of such cases from the special surgeon.

If these suggestions are acceptable to the Student's Welfare Committee, they may request the University authorities to adopt necessary measures and to instruct the medical colleges accordingly.

REDUCING SUBSTANCES IN THE URINE: THEIR DETECTION AND IDENTIFICATION.

By J. P. BOSE, M.B. (Cal.), F.C.S. (Lond.),

Mitra Research Scholar on Diabetes, Calcutta School of Tropical Medicine and Hygiene.

WHEN glucose is present in the urine in abnormal amounts its detection by any of the well-known tests is a simple matter. It is only when sugar is present in minute quantities that difficulty is experienced in its detection by one or other of the ordinary tests. It may be noted that Fehling's test is generally used and still considered by many to be practically infallible for the detection of sugar in the urine. But the fact that many substances other than glucose, often present in the urine, contribute to the reduction of the copper solution must not be lost sight of. It may further be observed that Fehling's test often gives fallacious results for

reasons which I shall deal with presently. In doubtful cases, therefore, it is always advisable to apply other tests such as Benedict's, Nylander's, the osazone test and polarimetric examination for confirmation or otherwise of the results obtained by Fehling's test. The object of this paper is to state briefly the nature of these reducing substances in the urine, the conditions under which they appear in it, and modes of differentiating them from glucose.

At St. Bartholomew's Hospital I conducted an investigation into the nature of these reducing substances in the urine in collaboration with Dr. Mackenzie Wallis, and we tried to find out a method by which we could remove these interfering substances from the urine and estimate the actual amount of glucose present in normal urine. We systematically applied all the classical tests I have mentioned above to every doubtful sample of urine that was sent to us, and on the findings of these tests we were able in most cases to decide definitely whether an abnormal amount of sugar was present in the sample or not. There were, however, instances when a sample of urine was found to give indefinite reductions by both Fehling's and Benedict's tests but yielded definite results by the osazone test. The question arises as to whether such cases are cases of true glycosuria or not. The determination of this point is often of great practical importance, not only for diagnostic purposes, and especially in cases of life insurance examinations, but also for the right interpretation of the glucose-tolerance test or in observing the effects of treatment. We also wanted to find out the line of demarcation, if any, between the normal sugar content of the urine (glycuresis of Benedict) and clinical glycosuria. This subject has attracted the attention of several observers for many years and it is beset with difficulties. The chief disturbing factor in all the methods which we tried was the presence of creatinine. In the method which we have now found, practically all the difficulties encountered have been overcome. The precipitating reagent which we have found to answer the purpose throws down all the creatinine from the urine, all the pigments, the greater part of the uric acid, urea and other interfering substances. Briefly, the method is as follows:—

REAGENTS AND APPARATUS REQUIRED.

(1) Boiling tubes of resistance glass with graduation marks at 12.5 and 25 c.c. The lower end of the tube is provided with a bulb of 4 c.c. capacity and a narrow neck above, 2 cm. in length and not more than 8 mm. in diameter. The bulb is designed to hold the mixture of the urinary filtrate and copper solution and the constricted neck serves to prevent reoxidation of the copper oxide by reducing the volume of the liquid exposed to the air in the tube above.

(2) A boiling water-bath with holes of a suitable size to hold the special boiling tubes in an upright position.

(3) Ostwald pipettes of 1 c.c. capacity.

(4) An alkaline copper solution made up as follows:—

Anhydrous sodium carbonate .. 40 grammes.
Tartaric acid .. 7.5 grammes.
Crystalline copper sulphate .. 4.5 grammes.
made up to a litre.

(5) Urinary precipitant.

Five grammes of pure phosphotungstic acid are placed in a 250 c.c. flask and dissolved in hot distilled water, 100 c.c. being used for the purpose. To this solution 12 c.c. of concentrated sulphuric acid (98 per cent.) is added drop by drop. When cool it is made up to the mark, filtered and stocked in amber-coloured bottles.

(6) Phospho-molybdic acid solution.

This is prepared by dissolving 35 grammes of pure molybdic acid (free from ammonia) in 200 c.c. of 10 per cent. NaOH. To this add 200 c.c. of distilled water and boil till all traces of ammonia are removed. Cool and then add 125 c.c. of phosphoric acid (85 per cent. strength) and finally make up in a 500 c.c. flask to the mark with distilled water. The solution should be of such a strength that 2 c.c. will completely discharge the blue colour from 2 c.c. of the copper solution.

(7) Standard 1 per cent. glucose solution. This is kept in the refrigerator and the fresh standard solution is made up each time by diluting 1 c.c. of this stock solution up to 50 c.c. in a measuring flask. Each c.c. of this standard solution contains 0.2 milligrammes of glucose.

(8) A good colorimeter, preferably of Kober type. The plungers in this instrument are fixed and the cups are movable. The sides of the plungers are of black glass as also the side of the cups and thus there is no space between the fluids and the prisms to allow of extraneous sources of light which introduce errors into instruments like the Duboscq colorimeter. Another advantage of the Kober instrument is that the standard solution can be fixed at any point and moved in relation to the unknown solution, thus enabling both strong and weak coloured to be compared with ease and accuracy. The depth of colour is proportional to the amount of sugar present and if the amount of sugar in one cup is known then the amount of sugar in the unknown can be easily calculated.

The estimation is carried out as follows:— Into a test tube measure out 1 c.c. of the urine by means of the Ostwald pipette and then add 2 c.c. of the sulphuric phospho-tungstic acid mixture. A dense precipitate appears of a reddish violet colour. The precipitate contains the creatinine, uric acid, urochrome and other pigments. Shake the test tube and then add 7 c.c. of distilled water to make the volume up to 10 c.c. Filter through a starch-free filter paper into a clean dry test tube.

1 c.c. of the clear filtrate is measured by means of an Ostwald pipette and placed in one of the special boiling tubes, and 2 c.c. of the alkaline

copper solution added. In another boiling tube place 1 c.c. of the diluted standard glucose solution and add 2 c.c. of the alkaline copper solution. To ensure mixing gently tap the bulb against the palm of the hand.

The two tubes are now inserted into a boiling water-bath and allowed to remain for exactly 6 minutes. They are then removed from the bath and 2 c.c. of phospho-molybdic acid solution added to each. A brisk effervescence occurs and in the presence of sugar a deep blue colour results, the depth of the colour depending on the amount of sugar present. The contents of both the standard and the unknown are now diluted with distilled water to the 12.5 c.c. mark and thoroughly mixed. The solutions are now placed in the two black cups and compared in the colorimeter.

Calculation.—Amount of urine taken = 0.1 c.c. (1 c.c. of 1 in 10).

Amount of glucoside present in standard = 0.2 mgm.

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \frac{0.2 \times 100}{0.1} = x \%$$

By this method the sugar in normal urine was found to vary in amount between 0.06 to 0.09 grammes per cent., and in 24 hours the total excretion of sugar by a healthy normal individual was found to be about 1 gramme.

Let us now discuss the merits and demerits of some of the common classical tests for the detection of abnormal amounts of sugar in the urine:—

Fehling's test.—Fallacies in Fehling's reaction are attributable to the following causes:—

(a) Some of the normal constituents of the urine such as uric acid, creatinine, etc., when present in excess reduce it.

(b) Sodium hydroxide when present in excess destroys small amounts of glucose.

(c) Conjugated glycuronates are hydrolyzed to reducing substances by NaOH.

(d) Lactose, which is often a normal constituent of the urine in women in the lactating period, also reduces Fehling's solution.

The same is true of pentoses, which, however, are rarely found in urine.

(e) The urea of the urine is sometimes converted into ammonia which dissolves the cuprous oxide and interferes with the delicacy of the test.

(f) Certain drugs eliminated by the kidneys such as chloral, copaiba, chloroform, benzoic acid, morphine, sulphonal, salicylates, etc., have a reducing action on Fehling's solution.

Benedict's test.—This is a comparatively recent test and has at present displaced nearly all other reduction tests for sugar. The substitution of sodium hydroxide by sodium carbonate overcomes the difficulties noted under the first three heads of the Fehling's test, as, urates, creatinine and conjugated glycuronates do not reduce copper in its presence. Then again the use of sodium citrate in Benedict's solution in

place of Rochelle salt renders the mixed solution perfectly stable, and it is always convenient to use one solution in place of two.

Another advantage of this test is that it at once tells us the approximate percentage of sugar in the urine from the character of the precipitate formed. Thus, if on boiling 5 c.c. of Benedict's solution with 8 drops of urine we get a light-green opacity, the sugar content is probably 0.1 per cent. If there is a green precipitate, the sugar content is between 0.1 per cent. to 0.5 per cent. In the case of a yellow precipitate, the sugar content is between 0.5 to 2 per cent. and in the case of a red precipitate it is 2 per cent. or over.

To a busy practitioner this test is of great value as it readily gives him a rough idea of the amount of sugar his patient is passing.

Benedict's test, however, does not exclude sugars other than glucose.

Nylander's test.—This test is a valuable negative test, a negative result indicating absence of glycosuria. But if a positive result is obtained it may be due either to glucose or some other substances as well. For this reason the positive results cannot be absolutely relied upon.

The fermentation test.—This test depends upon the fact that glucose is fermented by yeast with evolution of CO_2 and production of alcohol. The most convenient method of applying this test is to use one of the small Einhorn fermentation tubes which is so graduated as to give a reading of the percentage of sugar from the bulk of the CO_2 evolved.

Maltose and lævulose, if present in the urine, are also fermented by the yeast. Lactose is not fermented during the first 24 hours and glycuronic acid is not at all fermented by yeast. This is, therefore, a very reliable test for excluding reducing substances other than sugars.

The phenyl-hydrazin test.—This is a very reliable test for detection and identification of the different kinds of sugars which may be present in the urine. It may be noted that small quantities of iso-maltase, said to be present in normal urine do not yield crystals of phenyl-maltasazone. Glycuronates and lactose do not furnish crystals by this test under ordinary conditions. So that when properly carried out this is one of the best tests for identification of glucose in the urine. Although lævulose gives an osazone identical with phenyl-glucosazone, the two may be differentiated by the determination of their melting points. Crystals of phenyl-maltasazone can be distinguished microscopically by the fact that its yellow needles are shorter in length but much broader than those of phenyl-glucosazone.

Polarimetric determination. Before polarization the urine must be freed from proteins, uric acid, phosphates and colouring matters by precipitation with basic lead acetate.

The polarimeter indicating the different specific rotatory powers, dextro or lævo, of the various kinds of sugars helps to determine the particular one present in the urine. Thus glucose

has a specific rotatory power of $+52.7^\circ$; lævulose -93° ; lactose $+55^\circ$; maltose $+138^\circ$, etc. If, however, more than one sugar is present in the urine, polarimetric examination does not help us very much.

Let us now pass on to the consideration of some of the important abnormal constituents of urine which, acting as reducing agents, may be mistaken for sugar.

(1) *Glycuronic acid.*—It is closely related chemically to dextrose. The mode of its origin in the animal organism is believed to be due to partial oxidation of glucose. An inspection of their chemical formula will make the point clear.

(Glucose) (Glycuronic acid)

A substitution of an atom of oxygen for two of hydrogen in the first group will produce glycuronic acid.

It is supposed that glycuronic acid combines with the putrefactive bodies in the intestines as the sulphates do, and also with administered drugs such as chloral, morphia, antipyrin, antifebrin, pyramidon and is eliminated as conjugated glycuronates in the urine. Its function in this connection appears to be antidotal, the conjugated acids being harmless. The presence of conjugated glycuronic acid in the urine in abundance may thus be regarded as an effort of the system to overcome intoxication by combining with these toxic substances. In fact an increase of glycuronates in the urine is regarded by many as an important factor in the diagnosis of intestinal intoxication.

It has been shown by Myers and Neuberg that traces of glycuronic acid are present in normal urine in the form of phenol and indoxyl glycuronates. It has also been shown that glycuronic acid is a constituent of normal blood.

An increased amount of conjugated glycuronic acid is not only found in the urine of persons suffering from intestinal toxæmia but also in cases of chronic heart disease where the oxidising powers of the body is markedly reduced. In all these conditions it is quite probable that the increased production of the acid is due to an increased formation of indol and other aromatic bodies in the intestine, and it may be taken as an effort on the part of the organism to neutralize the toxic effects by conjugation with glycuronic acid. It is interesting to note that the ethereal sulphates, mainly excreted as indican, are also increased in such cases.

Diabetic urine not infrequently contains appreciable quantities of conjugate glycuronates, as is evidenced by the fact that after the glucose has been removed by fermentation, polarimetric examination will reveal a slight lævo-rotation. This lævo-rotation may also be due to oxybutyric acid which, however, is not precipitated by lead acetate whereas glycuronic acid is. So if lævo-rotation appears in the lead acetate filtrate it must be due to oxybutyric acid.

Tests for glycuronic acid.—The glycuronates give the same reactions as the pentoses. So Bial's test which is fairly reliable for pentoses cannot be fully depended upon when pentoses are present in the urine as well.

Bial's reagent is composed of 500 c.c. of strong HCl, 1 gramme of orcin and 25 drops of a 10 per cent. ferric chloride.

To do the test 5 c.c. of this reagent and 3 c.c. of the urine to be tested are placed in a test tube and heated to 95°C. over the flame till bubbles begin to rise, but not exactly to boiling stage. If a green precipitate is formed on cooling the presence of pentoses is suspected. If we further dissolve this precipitate in amyl alcohol and if spectroscopic examination shows characteristic absorption bands between the lines C and D, the presence of pentoses is confirmed.

If, however, the urine and the reagent have to be boiled for some time to get the reaction, it is probably due to glycuronic acid or conjugated glycuronates.

The phenyl-hydrazin test.—Glycuronic acid or conjugated glycuronates do not form an osazone by the ordinary method of heating on a water-bath for a short time. An osazone may, however, be formed by heating urine containing glycuronic acid with phenyl-hydrazin and glacial acetic acid for several days in an incubator at 40°C. The crystals so formed show as bundles of yellow needles with a melting point of 200 to 205°C.

Neuberg's test.—This is the most trustworthy test for identification of glycuronic acid.

The urine to be examined is heated in an autoclave for one to two hours at about 115°C. with sufficient sulphuric or phosphoric acid so that the fluid contains 1 to 2 per cent. After cooling the mixture is neutralized with sodium carbonate and immediately acidified with acetic acid and filtered: 250 c.c. of the filtrate is mixed with a hot aqueous solution of 5 grammes of para-bromophenyl-hydrazin hydrochloride and 6 grammes of sodium acetate. The mixture becomes cloudy after the addition of the reagent but on further heating the cloud disappears and in 5 to 10 minutes needle-shaped crystals are formed. The fluid should be allowed to cool and the crystals filtered off. The filtrate is again heated and after cooling a second crop of crystals is obtained. This process is repeated five times. The collected crystals are washed with absolute alcohol and then recrystallized several times from 60 per cent. alcohol in which they are soluble. The melting point of these para-bromophenyl-hydrazin crystals is 236°C. Besides the melting point the lævo-rotation of the osazone when in solution may also be taken as a proof of the presence of glycuronic acid.

(2) *Alkaptonuria.*—The presence of alkapton acids in the urine causes reduction in Fehling's solution, like sugar. Such urines when exposed to air and light turn black, especially if rendered alkaline. Alkaptonuria, according to Sir Achibald Garrod, "is not the manifestation of a

disease but is rather of the nature of an alternative course of metabolism, harmless and usually congenital and lifelong." Garrod thinks that persons suffering from alkaptonuria seem to be unable to break down the tyrosine in the protein molecule completely so that the intermediate product, homogentisic acid, appears in the urine.

These persons are usually healthy, though blackening of the cartilages and ligaments (ochronosis) and a progressive articular disease are seen in a few. Alkaptonuria, however, is a rare phenomenon.

The importance of recognising the presence of these acids in the urine lies in the fact that persons suffering from this disorder are often refused by life insurance companies, being supposed to have diabetes because of the marked reducing action of the alkapton acids on Fehling's solution.

To eliminate the fallacy one or other of the tests such as Nylander's, fermentation with yeast, the phenyl-hydrazin test and polarimetric examinations should be done. All of these will give negative results in the case of glycuronic acid. Secondly, when a dilute solution of ferric chloride is allowed to fall drop by drop into urine containing glycuronic acid each drop produces a transitory deep blue colour.

Garrod's test.—The urine is heated to boiling: 5 grammes of neutral lead acetate is added to each 100 c.c. of urine when a greyish precipitate is formed. This is filtered off and the filtrate kept in a cool place for 24 hours. If homogentisic acid is present it will separate out in combination with lead in a crystalline form.

The acid may be set free from the lead salt by suspending 5 grammes of the finely produced salt in 50 c.c. of ether and passing H₂S through. After filtering off the lead sulphide the ether is evaporated and crystals of the pure acid separate out and have a melting point of 147°C.

I shall now pass on to the consideration of the presence of sugars other than glucose in the urine, the causes of their appearance, and the tests by which they may be distinguished from one another. First:—

(1) *Lævulosemia.*—Lævulose is more frequently found in the urine of severe diabetics than is ordinarily supposed. The appearance of lævulose in the urine of diabetics is considered to be a bad sign. Diabetic patients as a rule can tolerate small amounts of lævulose, even when their power of assimilating glucose is practically lost. The explanation usually given is that the liver and the muscles can form glycogen much more easily from lævulose than from glucose and hence the former can be kept in store in the liver while the latter passes through into the general circulation.

It has been found by experiment that if we give 25 grammes of lævulose to a healthy normal individual and if we examine the blood for evidence of sugar at intervals of 15 minutes up to one hour, there is no rise in the blood-sugar at all. Whereas, if we repeat the same experiment

with the same amount of glucose there is a sharp rise in the blood-sugar content, which attains a maximum in half an hour but comes down to normal level in the course of an hour to an hour and a half.

The explanation usually put forward is that lævulose is at once taken up by the tissues and utilised, whereas a longer time is required for the utilisation of glucose, which thus lingers in the circulation.

It has been found, however, that in about 85 per cent. of persons suffering from diseases of the liver, the administration of a similar amount of lævulose is followed by a sharp rise in the blood-sugar in about 15 minutes to half an hour, gradually coming down at the end of the hour and followed by a marked lævulosuria. The lævulose-tolerance test, i.e., giving an individual 25 grammes of lævulose and estimating the blood-sugar 15 minutes, half an hour and one hour afterwards, has thus become very valuable for testing the functions of the liver. If the liver function is normal, there should be no rise in the blood-sugar at all, but if the liver function is inefficient, there will be a sharp rise as I have indicated above. I have done a very large number of liver function tests both in normal individuals and also in diseases of the liver such as cirrhosis, carcinoma, novarsenobillon poisoning, and have found the test to give very satisfactory indications of hepatic functions and adequacy.

Special test for lævulose.—To a few c.c. of urine in a test tube add an equal volume of 25 per cent. hydrochloric acid and a speck or two of resorcin. Heat to boiling, cool under the tap and transfer to an evaporating dish. Make the reaction alkaline by means of solid sodium hydroxide and return to a test tube. Add 3 c.c. of acetic ether (ethyl acetate) and shake. A yellow colouration in the acetic ether indicates the presence of lævulose.

(2) *Lactosuria.*—As I previously mentioned, lactose is often found in the urine of some women after childbirth. The sugar most frequently makes its appearance in the first few days after childbirth and in some cases it may continue to be present in the urine for a number of months after. Lactosuria is often most common about the third or fourth month after delivery.

Lactosuria is more common in women who do not nurse their babies. In women who nurse their children lactosuria may or may not appear, but if for any reason nursing is interrupted considerable quantities of lactose appear. The recognition of the presence of lactose in the urine in such cases is thus very important as an incorrect diagnosis of diabetes, based upon the discovery of a reducing sugar in the urine, is often made.

The reason why lactose appears in the urine of women in the post-partum period is due to the fact that it is absorbed into the blood directly from the secreting glands of the breast and

immediately excreted by the kidneys unchanged.

Tests.—Lactose in the urine can be differentiated from glucose by the fermentation test—preferably made with a pure culture of yeast. If a prompt fermentation takes place the sugar is presumably glucose or lævulose. If now we take a further sample and make a polariscopic examination a dextro-rotation will indicate the presence of glucose but a lævo-rotation will indicate the presence of lævulose.

If, however, no fermentation takes place by the pure culture of yeast, the presence of lactose or pentose is indicated. The latter, however, can be excluded by Bial's test.

The phenyl-hydrazin test.—As previously mentioned, lactose in the urine does not furnish a lactosazone by the ordinary method of carrying out the test. If, however, the specimen is concentrated and the residue extracted by heating with a considerable quantity of alcohol and then filtering and allowing the fluid to evaporate at room temperature, a relatively pure sugar will be obtained which gives a lactosazone which has a melting point of 200°C. The crystals are quite peculiar in shape, looking like tufts of silk threads.

(3) *Maltosuria.*—According to some observers in a good many cases of diseases of the pancreas—chiefly those with interstitial lesions—maltose has been detected in the urine. Rosenheim has reported a few cases of interstitial pancreatitis in which he got definite signs of maltosuria varying from 0.1 to 0.5 per cent.

It has also been shown that complete removal of the pancreas in dogs is accompanied by the excretion of maltose as well as of glucose.

Tests.—(1) Maltose, as I have mentioned before, yields typical phenyl-maltosazone crystals having a melting point of 207°C.

(2) Maltose will not reduce Barfoed's reagent (copper acetate); whereas the monosaccharids (glucose, lævulose, etc.), will.

(4) *Pentosuria.*—Pentoses, such as arabinose, xylose, rhamnose, etc., are carbohydrates containing 5 atoms of carbon in their molecules. Of these the arabinose variety is that most commonly found in the urine.

Pentoses make their appearance in the urine under three conditions:—(1) alimentary, (2) persistent or true pentosuria, and (3) mixed with glucose in cases of diabetes.

(1) *Alimentary pentosuria.*—This is sometimes seen after the ingestion of considerable quantities of certain fruits such as apples, cherries, pears, grapes, plums, etc. It has also been found in the urine of persons who drink beer heavily.

(2) *True pentosuria,* not depending upon the intake of large quantities of sugar, has also been described. These patients gave no symptom referable to diabetes. Some of them were victims to the morphia habit or were neurasthenics. Brat has reported two interesting cases in which a brother and sister suffered from

pentosuria. Bial has also reported three members of the same family as suffering from this disorder of metabolism. There is no record of any deaths from pentosuria and the pathology of the condition is still obscure.

(3) Traces of pentose have been demonstrated in the urine of a number of severe diabetic cases. It is not known whether the association of pentoses with glucose in the urine adds in any way to the severity of the case, as that of *lævulose* is supposed to do. It is believed that the deficient power of the tissues to oxidise glucose applies to pentoses as well.

TESTS FOR PENTOSE.

Tollens' test.—To 5 c.c. of urine add an equal volume of strong HCl and a little phloroglucin and heat the mixture on a boiling water-bath. A cherry red colour develops and the solution shows an absorption band between D and E. On cooling, a dark precipitate separates out which dissolves in strong alcohol, and this solution shews the colour and absorption band of the original mixture.

Bial's orcin test for pentoses has already been described.

A Mirror of Hospital Practice.

A CASE OF COBRA-BITE.

By A. H. HARTY,

CAPTAIN, I.M.S.,

Superintendent, Central Mental Hospital, Yeravda.

THE patient, a man named Mahadu Bala who is an insane patient in this Mental Hospital at 4 P.M. on 3rd December, 1925, saw a snake crossing one of the garden paths. He immediately rushed at it and seized it by the tail; the snake turned around and appeared to bite him, but he retained his hold and managed to grasp it firmly behind the head. Holding it in this manner he then threatened several of the patients, overseers and male nurses who naturally enough gave him a wide berth. The overseers and nurses tried every kind of persuasion to get him to release the snake, but he would listen to no one and for about twenty minutes ran about the grounds with the snake in his hand attempting to throw it on others. He now picked up a stone of moderate size and attempted to force it into the reptile's mouth, still retaining a firm grasp of it behind the head. Finally after creating considerable alarm he released it by throwing it on the ground. It was immediately killed and was identified as a cobra (*Naja tripudians*) 3 ft. 7 in. long. The soft parts of the mouth were considerably damaged by the stone which had been forced into its mouth and one of the poison fangs was broken off. As soon as he had released the snake the patient sat on the ground

and vomited and now showed that he had been bitten on two separate places on the left hand—one on the dorsum of the hand and the other on the outer aspect of the thumb.

At 4-30 P.M. a tourniquet was applied above the elbow, 40 c.c. of antivenene was given intravenously, and the punctures were incised and potassium permanganate crystals rubbed into the incisions.

5 P.M.—Sputum viscid, the patient using the fingers to clear it from the lips; complains of great pain in the arm and very restless—tossing about in bed.

5-15 P.M.—Speech becoming thick; pain severe in arm, asking to have the tourniquet removed.

Twenty grs. of calcium chloride given intravenously in 10 c.c. of water.

5-20 P.M.—Antivenene 10 c.c. given intravenously; it was intended to give 40 c.c. but the capsule broke in filling the syringe.

5-25 P.M.—Eyelids drooping; speech very thick, almost impossible to understand what he says; making signs to have the tourniquet removed.

6 P.M.—Unable to speak—very restless—pain in the arm very severe, sputum very thick and sticks to his lips and fingers. Makes signs instead of speaking. Well marked ptosis; commencing weakness in legs; drank a little water with difficulty and was given atropine sulphate grs. 1/50 hypodermically.

6-20 P.M.—Made signs for more water, but on attempting to drink it he indicated that it would not go down and the fluid returned through the nose. Pituitary extract 1 c.c. was given hypodermically.

6-30 P.M.—Insisted on getting up; he walked in a staggering manner to the latrine and passed a motion. The gait was very feeble and he dragged his toes.

6-45 P.M.—Antivenene 40 c.c. intravenously.

7 P.M.—Speech very bad, consisting only of a few sounds in the throat; not so restless, but respiration rapid.

8 P.M.—Speech still unintelligible; made another attempt to drink, but the fluid returned through nose as before.

9 P.M.—Speech improving, but not yet able to articulate. Drank water successfully.

10 P.M.—Asked for and ate an orange.

11 P.M.—Asked for tea and bread which he ate.

12 MIDNIGHT.—Can now speak quite distinctly. From now onwards he improved rapidly, but did not sleep at all the whole night. The pain in the hand became very severe in the early morning and at 10 A.M. on the 4th December, 1925, his temperature was 102°F., pulse 118.

During the next six days he ran a septic temperature. A large slough formed over the dorsum of the left hand and eventually all the long extensor tendons sloughed away for some 3 inches of their length. The hand became very septic and pus formation extended under the skin of the forearm up to the elbow. A long incision had to be made along the extensor aspect of the forearm to give exit to the pus. He had eusol baths twice daily and soon the parts began to granulate in a healthy manner.

On 20th January, 1926, the forearm had healed completely, but a portion of the dorsum of the hand was still open, but the skin was covering the granulations at a surprisingly rapid rate.

On 1st February, 1926, the wound on the dorsum was almost healed and no skin grafting was required. The fingers remained stiff and in extension.

An interesting point of the case is the fact that the man's mental condition has greatly improved, but I think it is merely a temporary improvement.

A CASE OF RECOVERY AFTER BITE BY A RUSSELL'S VIPER.

By K. V. RAJU,

M. & S. M. Railway Hospital, Guntakal.

C. A., a watchman, was bitten at 7 P.M. on the 29th December 1925, by a snake, on the right ankle which was bare at the time, and his friends brought him to hospital for admission. They also killed the snake which bit him, and brought it for identification. The snake was a Russell's viper, $2\frac{1}{2}$ feet in length.

The patient was admitted some 15 minutes after having been bitten. His condition on admission was anything but cheerful, as he was terrified of impending death. His friends, one and all, had collected around the patient and sympathised with him on his fatal misfortune, so that he was far from optimistic. Major Acton, in his lectures on snake-bite, used to say that some deaths from snake-bite were due solely to fear and shock, and with this comment in my mind, I tried to reassure the patient that the snake was not a lethal one, but he refused to be comforted.

On admission, he complained, amongst other matters, of acute pain in the part bitten—the right ankle,—tingling throughout the right leg, heaviness of the same limb, a sense of suffocation, an urgent inclination to vomit, and a fluttering sensation in the chest. His body was cold and clammy; temperature 98°F. , pulse 74—but feeble, respiration 13 p.m. He also complained of dryness of the tongue and thirst.

Having identified the snake, I immediately injected 35 c.c. of Kasauli antivenene intravenously. Locally at the site of the bite, I made a deep incision into the part bitten—which shewed clearly three fang puncture marks,—and cauterised the part with pure carbolic acid. The part was then bandaged.

At 9-30 the same evening the patient was better in every way, but complained of extreme pain in the back and shivering; his temperature had risen to 101°F. ,—probably as a result of reaction from shock. The subsequent course of the case was as follows:—

30th December.—Has slept well. Right ankle still very swollen and painful. Wound clean. Some fever— 101.2°F. —present, with accelerated pulse, 112.

31st December.—Much improved. As he has now survived 36 hours after the bite, his outlook is much more optimistic. Ankle still swollen and with a sanious discharge. Saline dressings applied.

1st January, 1926.—Very much better; discharged from hospital, and subsequently seen as an out-patient. Can now limp.

2nd January to 6th January.—Was seen each morning in out-patients, and walks daily half

a mile to and from the hospital. Wound healthy, but the ankle is still swollen.

7th January.—Lotio plumbi subacetatis dressings applied.

9th January.—Wound completely healed. The patient is now completely cured.

REMARKS.

(1) The immediate administration of antivenene intravenously appeared to have been an important element in his recovery; a second dose was not indicated, on carefully watching his symptoms.

(2) The local swelling and oozing of hæmolyzed blood was a marked feature of the case,—presumably owing to the thrombotic and hæmorrhagic action of the venom. Pain was a marked feature of the case. No subsequent gangrene was evident.

(3) The early symptoms were those of shock, probably due to fright and not to the action of the venom.

(4) Although three fang puncture marks were clearly visible, it is not certain that the viper had given a lethal dose of venom. On the other hand, the immediate administration of antivenene intravenously may have helped to save life. Had the patient been seen after a longer interval, a much larger dose of antivenene would probably have been required.

In conclusion, I desire to express my thanks to Dr. R. J. Dyson, District Medical Officer, for kind permission to publish the notes on this case, and to Dr. N. G. Rao, my colleague, for assistance with the patient.

A MURDER UNDER INSANE HALLUCINATION.

By Dr. SARASI LAL SARKAR,

Civil Surgeon, Noakhali.

THE modern development of psycho-pathology has revolutionised our former conceptions about insanity. The modern, present-day and intensive study of insane acts discloses the fact that terrible crimes, such as murder, are not really the motiveless acts that they often appear to be. The motive is there, but buried in the sub-conscious mind. The following case illustrates this:—

A young Sonthal, by name Supol, was brought to the Noakhali sub-jail for murdering in the street, without any apparent motive, a young Mahomedan boy, who was entirely unknown to him, and whom he then saw for the first time in his life. On examination, his general health was good, and there was no evidence of any organic or nervous system disease. His general demeanour, however, was that of a very absent-minded person, with vacant look, unconcerned as to his surroundings, yet answering questions truthfully, straight-forwardly and without circumlocution. From his confession made in court it appeared that the murder was entirely without

motive, that there was no attempt at concealment, no accomplices, no premeditation, and no repentance for the act, although a voluntary confession of the facts was made. The whole trend of the confession, in brief, shewed that the murder was committed in a fit of insanity.

An examination of the family history of the prisoner, however, threw a very full revelation upon the causes for the murder. His mother had four children, of whom the accused and a younger brother alone survived. After his father's death, she married Fudan Manjhi, a widower with one daughter and one son. The accused took a most intense dislike—even hatred—to this new step-brother. His mother now gave birth to a daughter, who died, as also did her second husband. She now absconded with a third mate, leaving her children at large and entirely uncared for.

The children were taken over by a brother of the second husband, a step-uncle, with the exception of the accused's younger brother, who was taken over by an aunt. The accused took refuge with a third person, Kanah Manjhi, who agreed to feed him in return for his carrying out household duties. Growing up in a casual and uncared for and random way, he drifted finally into the household of one, Raghu Manjhi, and when a youth became enamoured of a girl named Pendo, whom he used to visit stealthily at nights.

He was caught by the parents of the girl one night and compelled to marry her; also to furnish a dowry upon marriage, which he could ill afford.

He now went to live in his father-in-law's house, but soon quarrelled seriously with his relatives-in-law, especially with a young brother-in-law, aged about 12, and even with his wife. Fierce inter-family quarrels led to his being expelled from his house, and a threatened appeal to the police. He now became a wanderer at large.

A few days subsequent to this, he stated that he had a dream. "Mother Kali came to me in the night and told me to kill a man, and then go to Harishbhandrapur, where I will be a king there." The next morning he went out, committed the apparently motiveless murder, and when arrested by the police, explained that he was a king, with the powers to impose punishment.

In brief, the history of the patient's mental life reveals the causes underlying the motiveless murder. In his boyhood we have the intense hatred of his young step-brother, interfering with his affection for his step-sister. Later in life, hating his young brother-in-law and dispossessed of his wife, he was led in the realms of fancy to an imaginary exalted position in which he could be superior to all obstacles. Threatened with being made over to the Harishbhandrapur police, he became in fancy a king of the same place, with authority superior to that of the police. The Kali dream suggested the necessity to prove that authority; whilst his previous hatred of his step-brother and his brother-in-law,—both boys

—indicated that a boy of about that age should be the victim. The murder was, in effect, the satisfaction of a suppressed desire. It is curious that the accused told me that, when he went out armed with a sword to commit murder, the first person whom he met was an adult male, but that he left him alone. On meeting the murdered boy, he thought that the victim had been sent by the villagers as a sacrifice to his overwhelming authority.

The case illustrates the sub-conscious train of thought which led up to the act. That the patient was insane at the time when he committed the murder, I have no doubt at all.

A CASE OF TUBERCULOUS PNEUMONIA.

By V. N. DEUSKAR, L.C.P. & S., I.M.D.,

Haddo, Port Blair.

THE temperature chart shewn herewith is that of a strong, well-built Moplah prisoner admitted to Haddo Hospital on the 28th July, 1925, with malignant tertian malaria, subsequently complicated by pneumonia from which he died. The interesting features of the case were:—

- (1) Total absence of cough.
- (2) Total absence of all physical signs in the lungs, which appeared to be absolutely clear till the last.
- (3) Absence of "rusty" sputum and of hæmoptysis.

TEMPERATURE CHART.

NR. 45785. Date of arrival in Port Blair 28th 7th 25. Previous Admissions to Hospital: M.T. Malaria. I. Name: Toran Moideen. Date of Admission 28th 7th 25. B.T. Malaria. I. Age: 33-Years. Result Died 5th 8th 26. DISEASE: Intestinal Tuberculosis I. Pneumonia.

I may add that I have occasionally met with cases of pneumonia where physical signs in the chest were wanting, but never previously with one where cough was also totally absent. The case was definitely diagnosed as one of pneumonia on the seventh day after admission from the

following signs:—(a) flushed face; (b) laboured movements of the alae nasi; (c) quick pulse, and above all (d) hurried and uniformly accentuated respirations. The next day the patient passed twelve diarrhoeic motions in bed and became delirious. Two days later the delirium became worse, and he died at 12-40 noon, gasping for breath.

Post-Mortem Examination.—This shewed atypical pneumonia, probably of tubercular origin.

Findings.

- (1) Both lungs were full of miliary tubercles.
- (2) The pericardial sac contained 4 ozs. of clear serous fluid.
- (3) Both large and small intestine, but especially the large intestine, shewed scattered inflammatory patches of redness but not more than could be accounted for by the diarrhoea which developed on the patient's eighth day in hospital.
- (4) The peritoneum, the mesentery and the mesenteric glands were all normal.

The case is of interest as shewing how severe a pneumonia may develop of tuberculous origin with almost complete absence of all the customary physical signs of pneumonia.

My thanks are due to Dr. A. Bayley de Castro, Junior Medical Officer, Haddo, for his kind permission to publish notes on the case.

large within the previous three months, but he could not state when the goitre and exophthalmos had first appeared.

The case suggests one of Gull's disease,—viz., myxœdema associated with exophthalmic goitre, but there were no signs of generalised myx-

œdema. Gull's disease is stated to occur in adults, more often in women than in men; it

A CASE OF (?) MYXŒDEMA ASSOCIATED WITH EXOPHTHALMIC GOITRE.

By R. M. KAR, M.B., D.T.M. (Bengal),

Assistant Surgeon, Baripada P. O., Mayurbhanj State.

On the 6th January, 1926, an adult male patient came to the Sadar Hospital, Mayurbhanj State, and was admitted to hospital, but absconded the same evening, as he feared that surgical procedures were going to be resorted to. I was able before he left, however, to secure the two rather striking photographs sent herewith of his condition.

He was a well-built village cultivator, some 35 years of age, by caste a Bhuj, a local resident. He stated that no one in his village suffered from a similar complaint. He complained of two diffuse lipomatous-like growths, continuous one with the other by a similar but smaller swelling on the nape of the neck, situated over a bony growth arising from the seventh cervical spine. There was a further small flat lump on the back below the left scapula. The patient was otherwise well-built and shewed no tendency to diffuse subcutaneous deposit of fat elsewhere.

In addition, he had also enlargement of the thyroid gland, exophthalmos, tremor, and a mild degree of tachycardia. There were no signs of cretinism or imbecility and no family history of importance. The fatty swellings had first appeared two years previously, had grown very

may affect several members of the same family, and be hereditarily transmitted through the mother. Exophthalmic goitre may be associated with the myxœdema during the first part of the illness, and the disease is slowly progressive, extending over some 15 years or so. A condition of acute and temporary myxœdema, associated with exophthalmic goitre, has also been described. The rarity of the combination of the diffuse localised swellings with exophthalmic goitre has prompted me to publish these notes upon the case. The condition at least appears to have been either caused by or associated with endocrine deficiency.

(*Note*.—Possibly a case of diffuse lipoma associated with exophthalmic goitre. *Editor, I.M.G.*).

A REMARKABLE CASE OF PSEUDO. HYPERTROPHY.

By HARINANDAN PRASAD, B.Sc., M.B.,
House Physician, Patna General Hospital.

MOHAN, a Hindu male child, aged 8 years, was admitted to the Patna General Hospital on the 14th January, 1926, for the treatment of enlargement of certain muscles, which first started in the thigh about six years previously.

The patient's parents are living and healthy. He has no brother, but a living and healthy sister. There is no family history of such disease either on the paternal or the maternal side.

The patient is ill nourished, anæmic, of 49" in height and 23 seers in weight.

The muscles enlarged are the calves (but fairly strong), the quadriceps extensor, the flexors of the thigh, the glutei, the deltoid, the supra- and infra-spinatus and the erector spinæ.

The muscles atrophied are the pectoralis major, the trapezius and the latissimus dorsi.

The triceps have escaped but are very weak and the recti are separated with bulging in the upper part of the abdomen.

Electrical reaction is present but sluggish, the gait is waddling, lordosis present, loose shoulders are present so far so that the shoulders touched the ears on lifting the patient.

In attempting to assume the erect posture the patient turns over his belly, and proceeds in the usual way described in the books.

Measurements of some of the muscles are:—

Calf—14.2 in. (average normal 7 in.).

Thigh—15.5 in. (average normal 11 in.).

Deltoid 7 in. (average normal 6 in.).

Round the buttock 17 in. (average normal 14 in.).

Girth of abdomen 22 in. (average normal 19 in.).

The two photographs of the patient show the present condition of the different muscles clearly.

I must express my thanks to Colonel H. R. Dutton, I.M.S., the Principal of the Prince of

Wales Medical College and Superintendent of the Hospital and to Professor T. N. Banerjee, the Professor of Pharmacology and Visiting

Physician to the Hospital for their permission to publish in the journal.

Indian Medical Gazette.

APRIL.

THE CHANGING TIMES.

WE think that our readers will agree that Major Knowles and his small band of collaborators have earned the gratitude of the medical profession in India by bringing before them so clear an account of the advances which have been made in Indian medicine during the year 1925. The *Indian Medical Year*, published as a supplement to our issue of last month, is a post-graduate course in itself, and nobody has any excuse for failing to profit by it. In an hour or two at home, on a railway journey or even seated in his motor car the busiest practitioner can make himself familiar with the most important work in India of the previous year.

The younger generation of medical men does not always realise its special advantages and privileges. Even thirty years ago new discoveries of the greatest importance filtered very slowly from their source to the isolated practitioners who were waiting for them.

When Laveran announced the discovery of the malaria parasite, his reports were received with great scepticism by many, and some did not hesitate to call him a charlatan. The reason for this attitude of suspicion was the lack of training in microscopical technique; there were few medical men who were familiar with the appearance of normal blood even in the unstained condition.

When the parasite of kala-azar was detected its reception was very different; within a few months large numbers of medical workers confirmed the discovery, but even at that time there were few who were able or willing to make practical use of the discovery in the diagnosis of the disease, so that for several years kala-azar continued to exist in many places without being detected.

The wheels of progress have speeded up more and more; in the case of tropical medicine the pace has become exceptionally rapid. The number of research workers in tropical diseases has increased to a remarkable degree, there is better publicity for the results of investigations and the medical profession is now much more receptive of new discoveries than it used to be. Compare the slowness of the progress which was made during the ten years which followed the great discovery of Sir Ronald Ross with the rapid march of events in connection with kala-azar. It would almost appear that the work of Ross was a premature birth and that the world was not prepared to receive the great gift which was placed in its hands.

Although our knowledge of kala-azar is far less complete than is that of malaria, yet it is possible to claim that half of the persons who suffered from kala-azar in Assam in 1925 have had a course of treatment. The general public and the public health workers are straining at the leash, they are hardly prepared to wait for final proof of the sandfly transmission view of kala-azar, so eager are they to take action against the accused insect.

For years there have been periodical outbursts of impatience with the reluctance of Government to go full speed ahead with public health measures. Perhaps it may turn out that greater and more solid progress will be made if public health legislation be adopted in response to a demand by the people than if it were launched before the country is educated to a full realization of the necessity for action. The policy of Government appears to have been to create a suitable atmosphere by education and medical relief before taking action which would be likely to arouse opposition if it were forced on an unwilling or hostile community.

Even now the public demand is for medical relief rather than for public health measures and it is with some astonishment that we see highly trained medical men advocating a scheme for enlisting the services of indigenous practitioners with a view to providing medical relief for the whole population of India. Such schemes are more creditable to the hearts than to the heads of proposers and we are of opinion that it will be a black day for India if the forces of medical science are diverted to unscientific channels.

Those who advocate the collaboration of scientific medical men with the followers of the ancient systems claim that there is an insistent demand for the restoration of the old systems and that it is better to yield to this demand in such a way as to get half trained men rather than have to put up with untrained practitioners. It is true that there has been a vocal demand for the teaching of the old systems but we are suspicious of words which have no backing in action, and we find that there is much financial support for schools and colleges which teach scientific medicine, but very little for the Ayurvedic and Tibbi schools.

Also there is no scarcity of educated young men who desire to be trained in the medical schools and colleges and it would be indeed remarkable if it were found better to concentrate on the conversion or reformation of the practitioners of the ancient systems than to give instruction from the beginning on scientific lines to young men who have a good preliminary education.

Some Governments have been attracted by the glib promises of those who claim that efficient healers can be turned out much more cheaply by the followers of the ancient systems than by medical scientists, sad disillusion is bound to result. The next claim will be for equality of

treatment of both types of doctors, this means equality of financial aid, and the result will be that the Governments will have to pay more than before—for the production of chaos. The chief anxiety at the present time is not that medical men are so scarce, it is that there is a danger of their standards of education being too low and that the young practitioners may not be able to earn their bread and butter. It is now a question whether the time has not come for Government to survey the existing position and to decide whether public opinion is not ripe for an advance in public health measures rather than in pure medical relief.

It is also worth while to consider whether it would not be possible to increase the efficiency of the existing organisation of medical relief in such a way as to get twice or thrice the present results in exchange for a small additional expenditure. In many places there are dispensary buildings and trained doctors but the supply of quinine and other essential drugs is far too small. By giving the existing dispensaries adequate supplies of drugs and by insisting on periodical courses of post-graduate study for the doctors it would be easy to obtain vastly better results from the present organisation. This would be a safe and inexpensive experiment, whereas to desert the straight path of science would be exceedingly risky and exceedingly extravagant.

The scheme which is being tried in Madras is full of promise. This consists in giving a small subsidy to qualified practitioners to settle down in villages where no unaided medical man could earn a livelihood. This also is a safe and inexpensive experiment which we commend to the notice of all Governments.

For years we have been claiming that the medical problem of India is so vast and so complicated that a systematic survey of the position is essential. We have held that the problem is not merely one of medical relief and public health; agriculture, economics, social questions and education all form part and parcel of the great question of ill-health and inefficiency: for this reason a broad and comprehensive enquiry should precede the formation of a scheme. The welcome announcement of the intention to appoint a Commission to investigate agriculture arouses hopes that such an enquiry will be instituted, for the Commission will soon find that one of the greatest causes of the poverty of India is disease and malnutrition. We cannot conceive of the success of any policy which does not take into account the prevention of preventable disease. But if Government were to succeed beyond all reasonable expectation in increasing the productivity of the soil and in the prevention of disease, there will still remain the appalling problem of population and food supply; this has tacitly been ignored by all, but it will inevitably come into prominence, unless the people of India are educated to a sense of responsibility in the matter of blind and unrestrained reproduction. It will be a sad state of affairs

if we conquer disease and improve efficiency, only to find ourselves faced with the question of a population which is greatly in excess of the available food supply.

In a former editorial we expressed views on this subject which were regarded by some as being too optimistic. We held that when the people were educated in the prevention of disease and in the improvement of agriculture they would also automatically become capable of dealing with the problem of population, but we freely admit that our optimism was based on the experiences of western countries: there is no experience in the East to guide us in this matter. The only country in the East which has tackled preventable disease in a scientific manner is Japan, there the tendency to later marriages is quite definite, but in spite of this the increase in the population has been such that food shortage threatens to become a grave practical question in the near future.

The problem in India may not become acute within the present generation, but it is abundantly clear that if we interfere with the working of processes by which Nature has kept down the population by disease and war we must attend to the other aspect of the question and avoid allowing the population to grow out of proportion to the available food supply.

Enough has been written to show that it is not enough to control malaria and cholera and tuberculosis and the other great diseases, to do so might be possible. We have to avoid the error of thwarting murderous Nature in one direction, only to leave our flank exposed to a more terrible disaster. The attack by science on unfavourable environment must be wholly scientific, not half scientific. We are face to face with a difficult and dangerous situation: what we need is a well reasoned plan of action, not the impulsive and hasty efforts of impatient though well meaning enthusiasts.

Current Topics.

The General Medical Council and Indian Universities.

(Supplement to the *British Med. Jour.*,
Nov. 28, 1925, p. 187.)
Indian Universities.

THE Executive Committee have received communications from the University of Calcutta indicating that the syndicate are now prepared to receive a visitor or inspector of their M.B. examinations, whose report may enable the Committee to form an opinion concerning the "sufficiency" of that degree in terms of the Medical Acts. Colonel Needham, the official inspector approved by the Council, has accordingly been instructed to visit the examinations in question. His report, however, cannot reach the Committee until, at earliest, its meeting in February, 1926; and no decision as to the renewal of recognition can be reported to the Council before

the May session. Certain interim reports by Colonel Needham on other Indian universities and colleges have been received, and such action as the Committee deemed suitable has been taken thereupon. In particular, his report on the progress made by the University of the Punjab has justified the Committee in continuing for another year the recognition accorded to its degrees, under the same conditions as before.

The Intuitive Capacity of Children to Understand Spoken Language.

IN a very interesting article in the *British Journal of Psychology* (General Section), for July, 1925, Vol. XVI, Part I, Dr. J. W. Tomb, Chief Medical Officer of the Asansol Mines' Board of Health, discusses a subject which is of great interest to all English medical men and to all British mothers in India. Why is it that, whereas British parents in this country are usually only just able—or sometimes unable—to acquire a conversational knowledge of an Indian language, their children can often understand two or three Indian vernaculars simultaneously? The capacity of children to understand spoken language, he concludes, is intuitive and is not a function of intelligence; it is a function of the subconscious mind. Whereas the adult finds the greatest difficulty in learning a new language by the exercise of his reasoning and memorising faculties, the young child of 3 or 4 years of age picks it up intuitively.

Dr. Tomb's article is so interesting that we give it *in extenso* below,—with due acknowledgments to the *British Journal of Psychology*. His appeal for criticism and suggestions will probably not pass unnoticed by our readers. Incidentally, the article possibly throws some light upon better methods of teaching language study. The gramophone is now used frequently for lessons in foreign languages, whilst a recent amusing story in one of the popular magazines dealt with a "Nature" school for the study of languages; the student was led into a room in which was scenically depicted some common episode—a storm, a harvesting scene, or the like; his teacher depicted the moving scene to the student in the foreign language concerned, whilst the actual events happened before the student's eyes; unfortunately the "Nature School" proved financially a failure. The statement is often made that English children, born in India and fluent in an Indian vernacular, pick up that vernacular again with remarkable ease if they return to this country as young adults; but whether there is any real justification for that belief is doubtful. In any case, if Dr. Tomb is right, and if young children pick up a language purely intuitively—as they appear to do—this should profoundly modify methods of teaching such children, and "learning" a language should become a thing of the past in infant schools.

Dr. Tomb writes as follows:—

"No one living in a country such as India, where many different languages are spoken, can fail to be struck with the great facility with which European children pick up the many languages which they hear spoken around them, whilst their parents as a rule speak only one of these languages and that very imperfectly. To put forward a hypothesis to explain this striking state of affairs is the object of the present article.

It is commonly assumed that children learn a language as adults do, by the conscious memorising of parts of speech, moods, tenses, etc., but a moment's reflection will show that this cannot be so in the ordinary case of infants learning their mother-tongue, the parts of speech, moods, tenses, etc., of which cannot be consciously apprehended by them as such, or their use explained to them through the medium of language since they possess none. Moreover, children are universally able to converse freely in their mother-tongue without possessing any appreciation of its grammatical construction, which in civilised countries they afterwards have learnt by tedious years of study at school. Infants, therefore, must possess the capacity of intuitively bestowing the correct meanings on the sounds

(i.e., words) used in their hearing by their nurses, mothers, relatives, and other people.

In the district in Bengal in which the writer resides one frequently sees and hears English babies of from nine months to eighteen months old receiving directions and instructions from their mothers in English, from their *ayahs* in Bengali, from the house-servants in Hindustani, etc., the infants obviously understanding what is being said to them in each and all of these languages long before such infants are able to speak any of these languages themselves. It is also observable that infants appear to comprehend languages in whole sentences which they endeavour to reproduce *in extenso*, but owing to the undeveloped condition of their cerebral cortex and particularly of the speech centre, are unable to do so, merely as a rule producing some simple and easily articulated word belonging to the whole.

It is also a common experience in the district in which the writer lives to hear English children of three or four years old who have been born in the country conversing freely at different times with their parents in English, with their *ayahs* in Bengali, with the garden-coolies in Santali, and with the house-servants in Hindustani, while their parents have learnt with the aid of a *munshi*, and much laborious effort just sufficient Hindustani to comprehend what the house-servants are saying (provided they do not speak too quickly) and to issue simple orders to them connected with domestic affairs. It is even not unusual to see English parents in India unable to understand what their servants are saying to them in Hindustani, and being driven in consequence to bring along an English child of four or five years old, if available, to act as interpreter.

The writer recently became acquainted with a very interesting case of an English girl child aged four who had a Tamil-speaking *ayah* with her for two months only, her permanent *ayah*, a Bengali being ill. Within that period of time and without any apparent effort, the child was able to understand what the *ayah* was saying to her in Tamil and to converse with her in that language. It was moreover observed that the child even continued to speak occasionally in Tamil to the other servants for some time after her Tamil-speaking *ayah* had gone away, apparently not recognising that she was speaking to them in a language which they did not understand. Such a case as this can be satisfactorily explained only on the hypothesis that the child 'intuitively' and subconsciously placed the correct meanings on the various sounds (words) in Tamil which the *ayah* used to her in conversation, and was unaware of any difference between the various languages (English, Bengali, Santali, Hindustani, Tamil), which she was able to speak.

The writer has also observed many instances where English children of three or four years of age have been brought out to India by their parents, who themselves have come to India for the first time; such children after one year have in all instances acquired the capacity both to understand and to speak freely in all the vernaculars of the district they live in, whereas their parents, unless they have employed a teacher and deliberately studied one of the languages, are quite unable at the end of that time to understand what is said in any of them, and are only able to use a few essential and disconnected words, such as those for water, milk, food, chair, table, bed, etc. It is obvious, therefore, that a child's capacity for learning languages is of a subconscious nature and does not depend on 'intelligence,' for if the latter were the case it is reasonable to assume that the parents in such instances would pick up the various vernaculars more quickly than their children, whereas experience shows that the direct opposite occurs. Children must therefore possess the capacity of intuitively placing the correct meaning on spoken sounds, a capacity which they retain up to a certain age, but, in the majority of instances, lose altogether as they approach adult life. On no other hypothesis can the facts related above be intelligibly explained. The writer would welcome criticism of these views by others who, like himself, have had

an opportunity of studying how children in 'foreign' countries pick up the language or languages spoken around them there."

The Epidemiology of Cholera.

A VERY interesting memorandum on this subject is one by Major A. J. H. Russell, M.A., M.D., D.P.H., I.M.S., Director of Public Health, Madras, published as bulletin No. C. H. 339 of the League of Nations' Health Organisation, 1925.

In a historical introduction, Major Russell deals with the known history of cholera epidemics from ancient times until the present day. Cholera was known in India as early as the 14th century and in Europe from the 16th century onwards. In 1780 cholera destroyed some 20,000 persons at the Hardwar festival in India. As early as 1532 it was widespread in Java, India, Arabia and Morocco; in 1756 a vast pandemic occurred which lasted for some 30 years. In 1817 cholera seriously affected the army of Lord Hastings, collected to fight the Pindharis in Bengal, and the record of this outbreak constitutes the first collected account of the ravages of cholera in India. Since 1781 Eastern Bengal has apparently been the chief home and epidemic focus of the disease, whilst Madras has been chronically infected since 1757 or earlier. "Asiatic cholera"—widespread in epidemic after epidemic throughout the world—is undoubtedly of Asiatic origin; but it may be questioned whether there are not endemic foci in India outside Eastern Bengal. Even outside India itself some workers, such as Tholozan (1892) consider that endemic foci exist in Poland and Germany in Europe itself. Hart (1894)—bluntly asserts that the area of the Lower Ganges is the home of cholera for the whole world and that "Mecca is the centre of infection, and the progress of cholera in Egypt and Europe will never be checked until it is cleaned up." Colonel W. G. King, C.I.E., I.M.S. (retd.), also regards Eastern Bengal as the true endemic cholera focus for the whole world. "It is evident, from a review of the literature" writes Major Russell, "that India is considered to be one of the chief sources of infection, but it is not at all certain that Lower Bengal and the valley of the Ganges is the one and only endemic centre which it was commonly supposed to be.....it seems more reasonable to adopt Herbert's view that cholera 'is very generally endemic in some degree throughout the greater part of India.'"

Turning to the question of tracing different pandemics, we have Fayrer's figures for five pandemics from 1817 to 1887, all except one of which were traced to Indian sources. Simpson records nine pandemics between 1823 and 1912, chiefly affecting Persia, Turkey the Crimea, Greece and Morocco. Greig describes seven pandemics between 1826 and 1894 spreading sometimes over world-wide areas.

Modes of spread from India to the West have resulted in the suggestion that certain travelling routes have become crystallised; whereas in the Far East there appear to be not one but several endemic foci, the existence of which cannot be accounted for by importation from Eastern Bengal. Climatic factors are closely associated with cholera incidence and endemicity; whilst seasonal prevalence is a very marked feature of the disease in its epidemic manifestations.

Major Russell concludes his most interesting memoir as follows:—

"1. Cholera has existed in India for many centuries in much the same form as it exists at present.

2. The area of Lower Bengal and the Gangetic valley is not the one and only endemic centre for cholera in India. The disease is very generally endemic in some degree throughout the greater part of the whole peninsula.

3. Other endemic centres are to be found in Central Asia, in the Shat-el-Arab area, in certain parts of the Federated Malay States, in Java and the Dutch East Indies, in Indo-China, in the Philippines, and probably in Southern China.

4. The "latent" infection in the human "carrier," who is always present in endemic areas, only requires

"suitable conditions" in order to produce a fresh outburst of the disease.

5. A series of ten pandemics have been experienced since 1817, but the intervals between these invasions do not reveal any regular periodicity.

6. Mecca plays an all-important part in the spread of cholera through Western Asia, Northern Africa and Europe.

7. In six of the ten pandemics, cholera has followed the land route through Afghanistan or Persia and thence through the Caucasus and Transcaucasia to Russia and Western Europe. In the other instances, the disease has been carried via the Red Sea more or less directly to Egypt and thence to the whole basin of the Mediterranean.

8. The spread of cholera is greatly facilitated by the gathering of travellers at pilgrim centres, fairs and religious festivals.

9. The periodic outbursts of cholera in the countries of the Far East arise from the endemic foci known to exist in that area, and the infection need not necessarily be imported from India.

10. Many writers have attempted to demonstrate a relationship between the incidence of cholera and climatic factors, such as rainfall, humidity, temperature and pressure.

11. In Madras Presidency, the correlation between cholera and rainfall is highly significant, whilst the figures for humidity give either negative or insignificant correlation coefficients with cholera.

12. The seasonal prevalence of cholera is a recognised feature of the disease wherever it has been experienced.

13. The periodicity of cholera epidemics, which has been noted by various workers in different parts of the world, follows a definite 72-month cycle in Madras Presidency over the period 1902-21.

14. Famine or scarcity, with the resulting lowered vitality in the population, produces "suitable conditions" for epidemic outbursts of cholera.

15. Many problems in connection with the epidemiology of cholera still remain unsolved."

Tuberculosis in New York City.

IN contra-distinction to what obtains in India, we may contrast the strenuous efforts which have been put forward during recent years by the New York Tuberculosis and Health Association to rid New York of tuberculosis. Some idea of how very successful these efforts have been may be gathered from the following abstracts from their recent publications:—

"Recent studies of the New York Tuberculosis and Health Association show that striking progress has already been achieved in protecting childhood and saving lives. Secondly, additional knowledge and vantage ground has also been secured from which to attack the still remaining serious condition of tuberculous meningitis in children.

Mr. Drolet, the Statistician of the Research Service of this Association, points out that, whereas twenty-five years ago in New York City, when there were close on a million children under fifteen years of age, 1,370 deaths from tuberculosis occurred, in 1923 only 547 took place, though the child population had increased by almost three-quarters of a million (to 1,679,252)—a reduction in the death rate from 136 per 100,000 to 33, or by 78 per cent.

Mr. Drolet attributes in part the more effective prevention of tuberculosis first to the spread of knowledge about contagion and, secondly, to a number of important health measures which have removed in large part massive infection of children; namely, hospital care of the sick with segregation from their families; systematic disinfection, cleaning and renovation of the former homes of consumptives by the Health Department; examination of food handlers; and, above all, the practically general pasteurization of the milk supply.

Tuberculous meningitis, as Dr. Herben and Dr. Asserson point out, remains the most fatal form of tuberculosis that attacks children. They have collected valuable information concerning the outstanding facts of this serious condition from an intensive investigation made in co-operation with the Health Department of New York City. Institutions and homes were visited, hospital and tenement house records traced, autopsy findings collected and spinal fluids examined.

Dr. Herben and Dr. Asserson report that in tuberculous meningitis a history of contact with cases of active tuberculosis was found in the majority of cases. This form of infection was most prevalent in congested districts and in tenement houses. Most sources of infection were of a human type and only rarely milk-borne. Otitis media, measles, pneumonia and whooping cough in children in contact with active tuberculosis carry a particular menace; the largest mortality from tuberculous meningitis occurred in very young children. Cases among Italians were disproportionately high and springtime seemed the season of greatest mortality. In spinal fluid containing tubercle bacilli, 94 per cent. were of the human type and only 6 per cent. of the bovine.

The seriousness of tuberculous meningitis and the great rarity of recovery from it indicate the extreme importance of preventive measures against tuberculosis.

"More than \$200,000,000 have been invested in tuberculosis sanatoria and hospitals in the United States. There are nearly seven hundred institutions of this type and they make available sixty-six thousand beds for the sick from tuberculosis. Their annual maintenance alone amounts to almost \$75,000,000.

Tuberculosis sanatoria are the original corner stones upon which was built the now highly successful and life-saving movement represented by the organized anti-tuberculosis campaign in America. To what extent are these institutions now utilized, and are more needed or not? This is the definite practical subject to which Mr. Drolet, Statistician of the New York Tuberculosis and Health Association, has applied himself, and in his study of the "Recent Changes in Leading Causes of Death and their Bearing on Tuberculosis Hospitalization" he gives us the broad facts underlying the present tuberculosis and general health situation in this country.

From 1900 down to 1918 in the United States the tuberculosis mortality remained steadily around 150,000 deaths a year; thereafter this great loss was reduced and the deaths now number 100,000 annually. Since 1920 there has been an increase, especially due to after-war building of 30 per cent. in the number of tuberculosis beds in sanatoria, while the mortality was actually decreasing.

Between 1910 and 1922 tuberculosis in the United States passed from being the leading cause of death to fourth rank, being replaced by diseases of the heart. The general tuberculosis situation has been basically altered and, in the communities where there is already available a tuberculosis bed for each tuberculosis death, further enlargement of institutions, or building of new ones, instead of utilizing to fullest capacity existing facilities, is perhaps open to question. On the other hand, Mr Drolet's survey indicates that in only twelve states has this situation been reached, and there is still a deficiency of 39,000 tuberculosis beds in the remainder of the country.

After securing the establishment of tuberculosis institutions, and getting patients to utilize them, the greatest problem has been to retain the sick sufficiently long to achieve a cure or arrest of the disease. Mr. Bell and Mrs. Ilse of the Hospital Service, New York Tuberculosis and Health Association, describe the "Psycho-physiological Effect of Music on Tuberculosis Patients" from their practical knowledge of the value of music as an agency among tuberculosis patients to "dispel morbid thoughts, depressing mental conditions, and.....to bring contentment, renewed interest in life and a willingness to exert the will.....to fight the battle."

The Hospital Service of the New York Tuberculosis and Health Association, under their direction, has been responsible for the arranging during the past year of more than fifteen hundred musical performances, both in auditoriums, and in wards at the bedside of the sick in New York City's tuberculosis institutions, where close on 10,000 patients are reached annually. Mr. Bell and Mrs. Ilse conclude that appropriate music is "a vital and enduring element in tuberculosis treatment."

The Sanocrysin Treatment of Tuberculosis.

In the *Journal of Medical Missions in India* for November, 1925, Dr. C. Frimodt-Møller, Medical Superintendent of the Union Mission Tuberculosis Sanatorium, Madanapalle, gives the results of his experimental testing of this method in Indian subjects.

In 1890 Koch shewed that gold salts have an injurious action on cultures of the tubercle bacillus; subsequently Feldt introduced "Krysolgan," and J. B. White a double chloride of gold and sodium with manganese chloride. Walbum claims that the heavy metals, and especially gold have a stimulating effect on antitoxin production, when given in minute doses. Finally Möllgaard introduced "Sanocrysin,"—a double thiosulphate of sodium and gold. In a dilution of 1 in 100,000 this substance completely inhibits the growth of the tubercle bacillus in culture, although it does not kill the organism *in vitro*. On injection into animals its effects are comparable with those of tuberculin, a marked reaction being produced, with albuminuria and toxic myocarditis. The effects of this shock however can be neutralised by injection of an antitoxic serum containing antibodies. He concludes that "the combined sanocrysin and serum treatment is able to save the life of animals affected by even very grave miliary tuberculosis or tuberculous pneumonia, and to put them into a condition of clinical healing."

The experimental trial of sanocrysin treatment in man was therefore looked forward to very hopefully. In the first series of cases treated doses of from 0.50 to 1.5 grammes of sanocrysin were given intravenously at three-day intervals; a course consisting of 5 to 6 such injections. Severe reactions were observed in the majority of cases, however, and serum administration had to be resorted to whenever there were signs of shock, or when albuminuria resulted. On the whole the results were bad; some deaths occurred; in other patients the tuberculous condition flared up; in others symptoms of metallic poisoning were seen.

The treatment was accordingly modified. The injections are now given at intervals of a week; the doses ranging from 0.1 gramme to 1 gramme or less; and given only at a time when the patient is afebrile. A course consists of 10 to 12 injections and lasts some 3 or 4 months. The specific serum is used only in patients who shew shock or who suffer from albuminuria as the result of the earlier injections; a mild grade of albuminuria during the later injections not being of grave consequence. Further, sanocrysin treatment has often been combined with the induction of artificial pneumothorax. Cases for treatment should be early cases in the "exudative" phase, and should be carefully selected.

Under such controls, results are distinctly promising. Faber in July 1925, reported 42 rather advanced cases treated, with 8 cured and 17 very considerably improved. Begtrup-Hansen reported on 77 cases treated at different stages of the disease, of which 3 were much improved and 32 distinctly improved. Gravesen reported on 45 cases, of which 33 were arrested. Finally Faber sums up his results as follows:—

(1) Sanocrysin has a specific curative action on tuberculosis of the lungs. (2) It does not seem to have the same effect on extrathoracic localised tuberculosis (surgical tuberculosis, meningitis, etc.). (3) It is very effective on fresh tuberculosis of the lungs that has been manifested less than one year. (4) In older cases, the effect of the treatment is uncertain. (5) It is difficult to use it in febrile cases, but some good

results may be obtained in old cases of apyretic fibrous phthisis. So far it has not been able to cure acute lobar tuberculous pneumonia. (6) In ordinary cases a treatment lasts three to four months. (7) Generally the dangers may be avoided when the treatment is carried out in the right manner and with caution. (8) The antitoxic serum has a curative effect on acute shock. Its effect in preventing albuminuria is not clear, and further investigations are necessary."

At Madanapalle 20 patients were placed on the modified treatment, most of them—as is usual in Indian patients—rather advanced cases. Reporting in October 1925, the course of treatment had been completed in 4 of these patients, abandoned in 4 others, and was being continued in the remaining 12. Indian patients are not able to stand the doses given to European patients, and the doses given at Madanapalle have been 0.10 to 0.12 grm. as the initial dose, rising to not more than 0.5 grm. as a maximum. Although mild albuminuria has been seen, no patients have shown shock, or any alarming symptom, although febrile reactions have been frequently noted.

In the group of 4 cases who have completed treatment, the first patient after having been bed-ridden for over a year, can now go for walks, but tubercle bacilli are still present in the sputum; the second responded very well, far better than he had done to pneumothorax treatment, and can now go for walks; a third case was similar to the second; and the fourth is much improved. All four patients still show tubercle bacilli in the sputum however, although in greatly reduced numbers.

In the group of 4 cases where the treatment had to be discontinued, a febrile reaction or fever with albuminuria were the indications which led to treatment being discontinued.

Dr. Frimodt-Møller concludes that the sanocrysin treatment is at least an interesting one; but that the doses given to Indian patients should be far less than those for European patients; that cases must be carefully selected; and that the method calls for close individual attention to each patient to whom it is being administered.

Endocrine Therapy.

British Med. Jour., Dec. 5th, 1925.

At the Section of Medicine of the last annual meeting of the British Medical Association there was a discussion on the uses and abuses of endocrine therapy. Dr. Langdon Brown of St. Bartholomew's Hospital dealt mainly with the uses of endocrine therapy leaving the abuses to be discussed by others.

The ease with which thyroid extract is absorbed from the alimentary tract is probably due to the fact that the secretion of the gland entered this tract originally by the thyro-glossal duct.

The active principle of the thyroid, which is presumably thyroxin, is a general quickener of metabolism—"the draught to the fire"—and is the sole secretion providing iodine to the body. The doses formerly prescribed were too large. A total daily dose of 6 grains of the extract of fresh gland seldom needs to be exceeded, and it is wise to start with not more than $\frac{1}{2}$ grain three times a day. The extract of the desiccated gland is five times as strong as that of the fresh gland. It is worth while in children who fail to grow, who suffer persistently from nocturnal enuresis, who have night terrors, or who suffer from relaxation of the articular ligaments, causing knock-knee, painful heel, flat-foot, or lordosis, to look for stigmata of hypothyroidism, and if they are present to give thyroid extract. Whereas in children the thyroid is the great stimulant to growth, when this is complete its great function is a katabolic agent.

Parathyroid increases the calcium content of the blood, thereby having a sedative effect on nervous tissues, and promoting healing from the effects of chronic sepsis. It is useful in tetany, and sometimes in petit mal. It

is sometimes useful in chronic gastric ulcer, and others have found it useful in sprue and varicose ulcers. It is apparently capable of absorption when administered by the mouth and a rise in the calcium content of the blood follows its use. It is given in doses of one-tenth of a grain once to thrice a day.

The medulla of the adrenals yields an intensively active extract. Adrenalin is a general sympathetic stimulant which can be drawn on in an emergency. In asthma there is a paroxysmal spasm of plain muscle, resulting from vagal overaction. Adrenalin stimulates the antagonistic sympathetic and relieves the spasm. Surely this is not merely a coincidence. There is no satisfactory evidence that adrenalin is absorbed from the alimentary tract; possibly the local vaso-constriction which it excites prevents this. This limits its usefulness for oral administration to oesophageal spasm, gastrostaxis, and the relief of vomiting, in each of which it can act locally on the appropriate sympathetic endings. It can act also as a local vaso-constrictor on mucous membranes such as the conjunctiva and the nose, and appears to be absorbed from the latter. Injected subcutaneously or intravenously it can have a powerful effect in raising the blood pressure, augmenting the heart, relaxing the bronchial muscles, and converting glycogen into sugar. The drug is of little use in substitution therapy for the chronic adrenal lack of Addison's disease. For injection 3 to 5 minims are given for its local effects, by the mouth 10 to 30 minims of the 1 in 1,000 solution.

The anterior lobe of the pituitary gland is concerned with growth, and sexual development, but the active principle has not been isolated. It is usual to administer extracts of the anterior lobe by the mouth for conditions of insufficiency of this portion of the gland, and it certainly appears to have given results. Recent observations by Gardiner Hill show that anterior lobe extracts can promote growth either with or without simultaneous administration of thyroid extract, and that combined administration is more effective than that of either given separately. His results justify our giving the anterior lobe extract by mouth. Two grains thrice daily of the whole gland can be given. Intestinal atony can sometimes be relieved by oral administration of the posterior lobe. Its extracts may be absorbed by spraying into the nose or from plugs of cotton-wool soaked in a solution of the extract and inserted high up into the nasal cavity. This method has met with a fair degree of success in the treatment of diabetes insipidus by pituitrin. Intramuscular injections of $\frac{1}{2}$ to 1 c.c. of pituitrin will stimulate the muscles of the heart, intestine and uterus and will control polyuria.

The efficacy of insulin injections is beyond doubt; but that of any pancreatic extract orally administered is quite uncertain, to say the least. Its value in diabetes is generally admitted in the profession, though unfortunately much prejudice against it has been aroused by the statement that if a patient once starts insulin he must take it for the rest of his life. It is too soon to talk of the cure of diabetes but there have been a considerable number of patients who have had a course of insulin and who are now keeping free from glycosuria and with a normal blood sugar, although they have had no insulin for periods up to a year or more. Persistent hyperglycemia damages the cell islets, so that every case of diabetes must ultimately become pancreatic in character. Our aim should be to restore a normal blood sugar early enough to prevent permanent damage to the islets, and it is therefore important to use insulin as soon as the blood sugar fails to respond to dieting.

Ovarian extract has been shown experimentally to produce definite effects. The best results have hitherto been obtained in cases of ovarian inadequacy in earlier life. Successes have been reported with extract of *corpus luteum*, for the use of which there seems to be some rational basis. The efficacy of any orchitic extract given by the mouth is doubtful. Here the grafting method offers a better chance. There is no rational basis for the administration of thymic extract. Little is to be expected from pineal extract in sexual precocity and muscular dystrophies. Dr. Langdon Brown is entirely

sceptical as to the value of extracts other than those mentioned.

Dr. Swale Vincent on previous occasions has attacked the wholesale uncritical employment of animal products as drugs.

It is only when we are able to institute a true substitution therapy—artificially to replace the internal secretion of some ductless gland—that we have a right to use the expression "endocrine therapy."

It is universally recognized that thyroid gland and its various preparations are effective when given by the mouth. It is also generally admitted that insulin is not of any therapeutic use when orally administered. In regard to all the rest, a score or so of much-puffed preparations, there is very considerable doubt. Preparations of parathyroid, pituitary, and ovary are believed by many to be effective when given by the mouth, while the rest are only prescribed in this manner by the most optimistic and uncritical. It is to be noted, however, that this group includes a very large number of individuals.

Recent reports by responsible writers express considerable doubt as to the value of parathyroid extracts when given by the mouth. According to the statements of numerous writers the preparations given in this way are useful in parathyroid deficiency, nervous disorders, calcium deficiency, chronic toxæmias, etc. Many physicians prescribe small doses of adrenin to be taken by the mouth, though others express doubt as to the efficiency of this proceeding. The pituitary substance, various pancreatic preparations, extracts of ovary, corpus luteum, and mammary gland, are frequently given by the mouth and good results are reported by some observers. Oral administration of orchitic extracts is generally admitted to be useless. Among other organs and tissues, extracts of which are administered by the mouth, we need only mention thymus, pineal body, liver, spleen, kidneys. There is not the slightest reason to believe that these have any action in health or disease, and the same applies to still other substances which are advertised by the manufacturers of endocrine products.

In the case of all endocrine products except one as sold by the manufacturing druggists, there is no satisfactory evidence that any effects whatever are produced in healthy animals when they are given in the ordinary way by the mouth. It would be difficult to mention a drug which is clearly and beyond doubt of value in the treatment of disease and yet which produces no recognizable pharmacodynamical effects upon a healthy animal. In animals or in human beings suffering from insufficiency of secretion of a gland good results might accrue from an extract of the gland in question, while in a normal individual little or no effect might be observed.

It must, however, be remembered that insulin, adrenin, and thyroid extract have a powerful effect upon the normal animal. It will, then, not be unreasonable to regard with considerable suspicion the report that a pharmacologically inactive substance is of therapeutic value.

We do not yet know what is the function, or what are the functions, of the parathyroid glandules.

Most of the recent work has been devoted to the relation of the parathyroids to calcium metabolism. The results of parathyroid medication are still very uncertain. There has been too great a hurry to assume that all kinds of "tetanic" disorders are due to parathyroid lesion or dysfunction. It is by no means certain that any form of tetany is connected with the parathyroids except, indeed, that which sometimes occurs when the glandules are injured or removed during operations upon the thyroid.

In the case of the parathyroid, the ovary, and the pancreas, some special method of extraction is required in order to obtain preparations which display any physiological activity.

Collip has extracted from the parathyroid a principle which, on injection, prevents tetany for thirty hours in parathyroidectomized animals. The substance also produces a very marked increase in the blood calcium.

One of the most interesting items in Collip's communication is the statement that his extract is effective when administered by the mouth. He states most emphatically that he obtained negative results from all the commercial preparations he was able to test.

Parathyroid treatment has recently been recommended for the treatment of sprue. Scott reports excellent results after administration of parathyroid and calcium lactate. The blood calcium increased in accordance with the general improvement of the patients, but there is no statement that the author has tried the effects of calcium lactate without the parathyroid. It is, at any rate, not surprising to find that the administration of a salt of calcium may lead to an increase in the calcium content of the blood.

It is not yet possible to say what is the function of the pituitary body. The structure is composed of several parts, differing in origin, in structure, and presumably in function. Posterior lobe preparations contain principles which will raise the blood pressure and increase the flow of urine and produce other effects when injected into the circulation of an animal. Posterior lobe preparations are useful as drugs (when injected subcutaneously) in the treatment of diabetes insipidus and to aid the contraction of the uterus.

It is generally conceded that adrenal preparations have no effect of any kind in health or disease when they are given by the mouth. A possible exception may be admitted owing to the local action of adrenin on the lining membrane of the stomach. Extracts made from testis and ovary have not been found to produce any effects either in health or disease when given by the mouth.

According to Allen and his co-workers, injections of the extract into animals from which the ovaries have been extirpated produce not only the typical hyperæmia of œstrus, but also hypersecretion in the genital tract and growth of the mammary glands. No positive results were obtained with commercial extracts, nor were there any effects from oral administration.

Insulin ranks with thyroid substance as a means of employing a very valuable substitution therapy. Although the best known and most reliable preparations have to be given by subcutaneous injection, several observers claim that their special substances are effective when given by the mouth.

Dr. H. Gardiner-Hill discussed the value of thyroid extract in obesity and called attention to the way its action could be augmented in certain cases by the simultaneous administration of whole-gland pituitary extract.

By administration of thyroid and whole-gland pituitary extracts simultaneously the beneficial effects of thyroid extract can be obtained without its attendant disadvantages, and a considerable improvement in metabolism and loss of weight occurs. This improvement in metabolism, however, is not maintained for any length of time when treatment is discontinued; sooner or later it reverts to its former state and the patients again gain weight. It does, however, seem possible, when once the weight has been reduced, to maintain the new level of metabolism on decreased doses, and by alternating periods on and off treatment to help these patients considerably.

Desiccated extracts of thyroid and whole-gland pituitary are used and given in doses gradually increased at fortnightly intervals, starting with half a grain of each a day and working up to a point where the patient loses one or two pounds a week. Estimations of the sugar tolerance are made at frequent intervals to control the dosage.

The method of administering thyroid and pituitary extracts simultaneously has also been made use of in certain cases of adolescent goitre. Pituitary extract by itself has no apparent effect on these goitres; if given with thyroid extract the beneficial effect of the latter seems to be enhanced.

Dr. Gardiner-Hill also referred to the value of thyroid and pituitary extracts in the treatment of undergrown children. He cited the case of a girl with juvenile myxœdema, whom he had been treating for the past

three years. Her rate of growth on thyroid extract was more than five times as great as her rate of growth when this treatment was discontinued.

The value of anterior lobe pituitary extract given by the mouth is not generally appreciated. He has several children under treatment with combined thyroid and anterior lobe pituitary extracts, and the resulting increase in growth is greater than in the cases where either of these extracts have been given alone. Estimations of the sugar tolerance again show that in these children also the carbohydrate metabolism is considerably improved by treatment.

Mr. Kenneth M. Walker dealt with the surgical aspect of endocrine therapy—the attempt to remedy deficiencies in the endocrine system by means of grafts.

When donors of a different subspecies or species are employed the absorption of the graft is so rapid that the operation is useless. Indeed, it is probable that in human surgery the use of grafts obtained from such animals as a sheep or a goat is no more effective than the employment of injections of emulsified gland. This being so, if tissue from the lower animals is to be used it is better to follow the technique of Stanley and Kelker and inject fragments of solid gland through a large calibre needle rather than to perform an open operation. Voronoff in his work on testicular grafts, has made extensive use of monkeys, and has justified his choice on the ground that man and the anthropoids are very closely allied in their serum reactions (both agglutination and precipitation). But while it is better to obtain grafts from the higher than from the lower branches of the monkey family, in any case a rapid absorption of such grafts must occur. The only hope of effective work in endocrine transplants lies in the obtaining of material from a human source.

Halstead has stated that grafts do not ordinarily survive unless there is a pre-existing physiological deficiency in the host of the gland in question. For example, transplants of testicle will only succeed in cases of eunuchoidism. Should the animal be fully sexed the grafts will not survive. Still less is a graft capable of surviving when it is exposed to the action of an opposing gland. Thus Steinach found in his masculinization and feminization experiments that it was impossible to engraft an ovary on a male rat or a testis on a female unless the animals had previously been castrated.

In interpreting the results obtained from grafts it is necessary to maintain a strictly critical attitude. Even when an effect has been demonstrated, it must be remembered that the life of the graft, except possibly in the case of an auto-graft, is a limited one, and that sooner or later, and almost certainly within the space of three years, all the transplanted tissue will have disappeared. And what is true of testicular grafts is equally true of transplants of other endocrine glands. Kocher, a pioneer in thyroid grafting, gave it as his belief that it is not possible to obtain permanent relief by such methods. In the cases of glands other than the thyroid and the gonads, the results of transplantation will be found to be still less favourable.

The Treatment of Asthma.

British Med. Jour., Aug. 29, 1925.

In the discussion on the treatment of asthma at the last annual meeting of the British Medical Association, Dr. E. P. Poulton (London), defined asthma as a bronchial spasm and a vaso-motor turbulence and said that there were several causes of this condition. He urged that asthma due to infection, whether from bronchitis or nasal catarrh, or the cardiac asthma of elderly patients (best treated by morphine or oxygen), should be sharply separated from the "allergic" type of asthma due to hypersensitiveness. This group, included, besides asthma, the other well known toxic idiopathies. They must admit with van Leeuwen that skin reactions were of no value in diagnosing the cause of the asthmatic attacks, but his extract of human dandruff might be of great value in determining whether

a case was really allergic, and, besides asthma, it might be used to separate off the allergic cases of epilepsy, migraine, urticaria, and so on, from the remainder of these groups. Asthma was not due to anaphylaxis any more than histamine shock was due to anaphylaxis. The very fact that allergic individuals might be sensitive to drugs, such as aspirin, was also a proof of this. The treatment might be directed to (1) the condition of the patient—specific or non-specific—as described by Dr. Langdon Brown; (2) keeping away from the specific exciting substance by going to Switzerland or other places where it did not occur; (3) to altering the receiving mucous membrane of the nose—for example, by touching certain spots with a cauterizer; (4) altering the condition of the bronchial muscles by subcutaneous injections of 1 to 5 minims of adrenaline to stop spasm, or 1 to 3 minims of caffeine, or by oxygen inhalation. He suggested that the psychic factor had been exaggerated, and was merely subsidiary in causing attacks when the other factors, the exciting substances and so on, were also present. In a similar way an attack of angina or diabetic coma might be precipitated by an emotional disturbance.

Dr. P. Hamill (London) said that it would be borne in mind that sensitivity to bacterial proteins could occur, and probably this was in part, at least, the cause of the asthmatic attacks of elderly chronic bronchitics. It was important in all cases to examine the sputum. Where the dominant infection was the *M. catarrhalis* immunization by means of vaccines was often strikingly successful. In pneumococcal cases the benefit might be considerable, but the immunity was short-lived and courses of inoculation needed to be repeated at intervals. Chronic bacterial infection rendered the patient more susceptible to foreign protein, either by maintaining sensitivity or exhausting the defensive mechanism (exhaustion of the sympathetic and its associated endocrines). Accordingly, attention should be paid to the respiratory tract as a whole, the upper air passages should be carefully examined for evidence of sinus disorders, and any defects or chronic infection dealt with. Dusty occupations should be avoided. Bronchitic infections should be treated specifically, a matter of great importance in avoiding secondary effects and changes in the lungs.

The bronchioles could be relaxed by paralysing the vagal terminations (atropine or hyoscine), by stimulating the sympathetic (adrenaline or cocaine), and by relaxing the plain muscle (amyl nitrite, benzyl benzoate, papaverine). The drugs could be administered by injection (atropine, hyoscine, adrenaline, papaverine, caffeine); by inhalation or spray (atropine, cocaine, adrenaline, nitrites, benzyl esters); asthma powders should be avoided, for the smoke tended to set up bronchitis; and by mouth (atropine, belladonna, etc., benzyl benzoate).

Probably of all remedies the most valuable was a hypodermic of adrenaline 1 to 2 minims, with or without pituitrin at the first onset of distress.

Dr. A. F. Hurst (London) said that during the thirty years he had suffered from asthma he had learnt how to avoid it and how to treat it when it came, but he was still asthmatic. He believed that the authors who from time to time announced that they had discovered a cure for asthma had made this mistake.

The only cure of asthma was not to have it.

An hour's rest before dinner, a complete rest from work each week-end, and at least two holidays of not less than three weeks' duration every year would do much to damp the activity of the asthma centre. The ideal holiday was Switzerland in the winter. An asthmatic, who for weeks had scarcely been able to crawl from one room to another without panting, found himself after a couple of days able to ski, luge, and skate as well as any man of his age. He was, moreover, able to eat anything and to do anything with impunity, as the chemical and reflex causes of his asthma were only operative when his asthma centre was tired and irritable. On returning home he was likely to have three or four months of almost complete freedom before he gradually became fatigued and once more

subject to asthma on exposure to the various exciting causes which operated in his case.

Every asthmatic owed a debt of gratitude to Dr. Brian Melland of Altringham, whose discovery in 1910 that adrenaline could stop an attack was the one great advance in the treatment of asthma since Sir John Floyer wrote his monograph on the subject over two hundred years ago. Dr. Hurst had developed the technique of the adrenaline treatment in his own case and in that of numerous patients who had come under his care, with the result that he believed it was quite unnecessary ever to have a bad night as a result of asthma. It was essential that the injection should be given directly the attack began; during the night it should be given the moment the patient was sufficiently awake to realize that he required it. Adrenaline was the only drug administered subcutaneously which he always advised the patient to give himself, as otherwise it was impossible to inject it sufficiently promptly. If given without delay, the patient was often asleep in less than five minutes from the moment he woke feeling dyspnoic. Used in this way very small doses were sufficient. The speaker never gave himself more than 1 minim of 1 in 1,000 solution of adrenaline chloride, and he had rarely found a patient who required more than 3 minims, although in many instances he had been told by the patient's doctor that 5, 10, or 15 minims were needed or that adrenaline was entirely without effect. This was always due to the fact that it had not been injected until the attack was at its height. Under such conditions 15 minims might produce no other effect than tachycardia, tremor, and a feeling of collapse, whereas, given at the onset, 1 or 2 minims would have completely aborted the attack, without even producing any rise of blood pressure.

"The Treatment of Leprosy: A Suggestion"

IN the *Ceylon Journal of Science*, Section D—Medical, for the 2nd November 1925, Dr. L. Fabian Hirst, M.D. (Lond.), the well known microbiologist to the city of Colombo, puts forward the suggestion that chaulmoogra oils and similar products irradiated—(one presumes by ultra-violet or similar rays)—may be far more potent than the expressed oils themselves, or their ethyl esters. Dr. Muir has recently shewn that fresh cold-drawn oil of *Hydnocarpus wightiana* is the cheapest and best product for subcutaneous injection. May it not be that intense solar radiation in tropical forests may be responsible for this? Olive oil, when irradiated, acquires highly anti-rachitic powers. Fish oils owe their high anti-rachitic power to their high content of vitamins, due to ultimate absorption of such products from the vegetable kingdom. Fats rich in vitamin A are of value in the treatment of tuberculosis. He suggests that "we have only to compare the therapeutic efficiency of *Hydnocarpus* oil in a high energy phase with that of the same substance in a low phase in two parallel series of cases of leprosy..... It may be possible to reactivate degraded anti-leprotic oil by appropriate physical means."

"International Critical Tables."

THE National Academy of Sciences and the National Research Council of the United States is about to publish a monumental work dealing with the above subject. The following is a short account of this forthcoming publication, which will be of interest to all laboratory and biochemical workers:—

"The material contained in International Critical Tables has been collected and critically evaluated by some 300 co-operating experts, including chemists, physicists, and engineers of the United States, Canada, Great Britain, Belgium, France, Italy, Austria, Germany, Denmark, Switzerland, Holland, Australia, and Japan.

The editorial expenses (about \$170,000) have been contributed by American industrial firms and benevolent foundations. The work of the co-operating experts, which is practically gratuitous, may be assigned a money

equivalent of not less than \$300,000. The cost of printing and distribution will be about \$100,000 and the whole undertaking represents a money value of at least \$570,000, of which the returns from subscriptions will represent only a minor part.

The scope of the material collected covers all available information of value concerning the physical properties and numerical characteristics of (a) pure substances; (b) mixtures of definite composition; (c) the important classes of industrial materials; (d) many natural materials and products; and (e) selected data for selected bodies or systems, such as the earth and its main physical sub-divisions and the solar and stellar systems. Publications of the world in all languages have been combed for data and much unpublished information has also been collected.

In addition to their wide scope, the Tables will contain many novel features of arrangement. Thus, for example, not only will it be possible to find readily all of the properties of a given substance or material, but it will also be possible in many cases to ascertain readily what substance or material of a given kind has a maximum, a minimum, or a given value for any given property. This feature will be of great assistance in identifying a substance by means of its properties or in selecting a substance or material on the basis of a given property or combination of properties.

The principal language employed will be English; but much of the explanatory text, the tables of contents, and the very complete index, will be given also in French, German, and Italian.

The work will be issued in five volumes, comprising an estimated 2500 pages (8½ by 11 inches), and the editors are making every effort to compress the material which has been collected into the available 2500 pages. All volumes will be bound in a uniform reinforced buckram binding, and will be delivered to all advance subscribers as issued, with packing and carriage charges prepaid.

1. "International Critical Tables" will be published at the price of \$60 for the five-volume set, at which price all orders placed directly with the publishers will be filled.

2. Until the appearance of Volume One (early in 1926) but not thereafter, the following classes of persons and institutions shall have the right to subscribe at the rate of \$35 for the set of five volumes.

a. Individuals who are members of a recognized scientific or technical society; but only one set may be subscribed for by one individual.

b. Educational institutions, public libraries, government departments, research laboratories, and the libraries of industries. Such organizations may purchase a number of sets if required for their own use.

3. No orders can be accepted from or through book dealers or agents at the pre-publication price."

The Standardisation of Bacterial Vaccines.

IN the *Lancet* for October 31st, 1925, Major H. C. Brown, I.M.S. (retd.), of the Wellcome Bureau of Scientific Research, returns to this subject, which he and Major Kirwan, I.M.S. made particularly their own when they published their method of standardisation by the use of opacity tubes containing suspensions of barium sulphate of different strengths.

In theory, says Major Brown, the ideal way to standardise a bacterial vaccine would be in terms of weight of dried bacterial substance, and in his paper of 1919 he gave such a table, shewing the correlation between weight of dried bacterial substance, number of organisms, and opacity. Lieut.-Col. J. Cunningham, I.M.S. and Sub-Assistant Surgeon B. Timothy, L.M.P. in a paper in the *Indian Journal of Medical Research* (1924), tested the value of Brown and Kirwan's opacity tubes, by an exhaustive piece of work with the hæmocytometer. They found, in common with Brown and Kirwan, that size of the bacteria worked with is of great importance in standardising. Thus for the same opacity, there are 2.9 times as many cholera vibrios,

and three times as many *B. influenza* (Pfeiffer) as there are *B. coli*.

The method introduced by McFarland however ignores this very important point. To sum up, the opacity method used in conjunction with Cunningham and Timothy's exhaustive table of relationship between different opacities and number of organisms of different species—as determined by the hæmocytometer, is the readiest, simplest and most reliable method to utilise. "It is hoped that one man's million will no longer be another man's thousand."

Artificial Sunlight in Dermatology.

IN the *Transactions and Fourteenth Annual Report of the London Dermatological Society*, 1925, p. 17, Dr. F. Howard Humphris gives an interesting analysis of results in the use of ultra-violet radiation in different diseases of the skin. The degree of reaction is taken as the standard for dosage; thus with a first degree erythema, there is no visible exfoliation, and treatment can be given daily; the second degree approximates to mild sunburn; in the third degree the reaction is that of intense sunburn, the epidermis peeling off in strips; in the fourth degree, there is blister formation. The first and second degree treatments aim at a bactericidal effect; that of the third degree at an additional hyperæmic reaction.

Lupus is, of course, the chief disease which has been treated by ultra-violet radiation, but Dr. Humphris claims that there are many other conditions amenable to the same treatment. In acne the method gives clean results with marked improvement, and is free from the danger of burns encountered with x-rays. In alopecia areata results are excellent, and treatment with the Kromayer lamp has almost become the standard treatment for this condition in America; the results as compared to those by previous methods are almost revolutionary. Boils and carbuncles can be aborted by a single exposure so given as to secure a reactionary erythema in the part affected, whilst if pus has formed and has been evacuated, exposure to ultra-violet light will hasten healing and prevent a further crop of boils. In herpes the method greatly relieves pain and lessens subsequent scarring. In impetigo results are good, but only if the local condition has been thoroughly cleansed previously, and all crusts, etc., removed. Lichen planus, which is usually rendered worse by exposure to x-rays, is very amenable to ultra-violet radiation; the intense irritation is at once removed. In three cases of oriental sore complete healing took place, whilst telangiectases can often be cured by the treatment.

In lupus, Dr. Sequeria, after nearly a quarter of a century's experience of the use of ultra-violet radiation states that the "results continue to be of a highly satisfactory character." The dry type of lupus alone is suitable for ultra-violet radiation, and this is fortunate, because it is in precisely this type of lupus that x-rays are absolutely contra-indicated, as their use may lead to the development of carcinoma. In ulcerative lupus, on the other hand, x-rays are invaluable. In addition to local ultra-violet radiation, the whole body should be exposed to the rays of the carbon arc; some 90 per cent. of cures can thus be brought about.

In nævus the cosmetic results are excellent; the treatment is painless and therefore well adapted for babies and young children; there is no scarring, and even scars which are the result of the previous application of caustics may be much improved. Onychia is a disease which is very intractable to different forms of treatment, but very amenable to ultra-violet radiation; in one instance a patient was considering giving up his profession—that of a dentist—on account of this condition, but was cured with five treatments. For chilblains the method should be combined with the use of melted paraffin wax baths. Results are good in the classical type of psoriasis if all pastes and ointments, etc., are carefully cleansed off before exposures are made, and if exposures are combined with general exposures of the whole body to ultra-violet light. Pruritus ani et

vulvæ often clears up completely, but careful preparation of the patients is necessary; all hair must be cut short or shaved and the parts smoothed out with gloved hands in order that the rays may penetrate to all folds and recesses; reaction may be severe, but improvement is marked. In infections with tinea versicolor one or two applications of the Kromayer lamp in contact will usually cure the case. In urticaria in general the radiation relieves the irritation. Chronic ulcers of all kinds, including those associated with varicose veins and following x-ray dermatitis are claimed to respond more quickly to ultra-violet radiation than to any other form of treatment; a weekly exposure sufficient to produce a definite degree of erythema is soon followed by healing.

An interesting discussion followed the reading of Dr. Humphris' paper. Dr. Bunch commented on the work of Rollier at Leysin. General body exposure to artificial sunlight greatly improves bodily metabolism; whilst he prefers to stop short of producing erythema when using the application locally. Dr. Orlebar noted that ultra-violet radiation increases the calcium content of the blood, and suggested that this aspect of the matter should be investigated. Dr. Knyvett Gordon, as a pathologist, asked how the rays act; he was far from certain of their bactericidal action; they do not penetrate the dermis, and possibly their good results are due to the hyperæmia inducing local leucocytosis. Dr. Knowsley Sibley said that the rays were not bactericidal in lupus but probably induced a stimulation of phagocytosis locally. The question of dosage was very important; it must be studied for each individual case. His experience of the method with cases of telangiectasis had been very successful.

Radiographic Diagnosis of Perforated Peptic Ulcer.

Jl. American Med. Assn., Dec. 12th, 1925.

DR. R. T. Vaughan and W. A. Brams of Chicago by the use of the fluoroscope have been able to detect free air in the peritoneal cavity in 86.2 per cent. of series of 29 proved cases of acute perforation of peptic ulcer. No special preparation is needed, the sign may be present as early as two hours after perforation. The air may be seen between the viscera and the abdominal wall or between the diaphragm and the upper surface of the liver.

When a competent radiologist is available this method of examination may be of great service as an addition to the existing means of diagnosis in cases of perforation of the stomach or intestine.

German Medical Ethics.

Lancet, Oct. 24th, 1925.

At the annual meeting of the Deutscher-Aerzte-Vereinsbund, 267 delegates were present, representing medical societies and local branches with a total membership of 33,581. The meeting discussed the suggested codification of medical etiquette.

The proposal contained rules on professional secrecy, on advertising, and on the question of the qualification of specialists. The sale and the purchase of a medical practice is held to be unprofessional except in cases where the widow or the children of a deceased medical man offer his practice for sale. It is further unprofessional to criticise other medical men, to give medical advice, or to practise during a holiday stay in a health resort where other medical men are settled, and to give testimonials for "secret" medicines. The establishment of a joint practice is allowed only between specialists of the same branch or between general practitioners, but not between a specialist and a general practitioner. Canvassing is strictly forbidden and contracts allowed only under special rules.

The reform of the German criminal code was then discussed from a medical point of view. The principal

items of medical interest are that a criminal shall be held responsible for his actions even when in a state of diminished consciousness caused by drunkenness, drunkenness being no longer regarded as an extenuating circumstance. Drunkards shall be subjected to special measures, such as compulsory detention in an asylum, prohibition to obtain intoxicating liquor, loss of civil and voting rights. Other items of interest deal with homosexuality which shall continue to be a criminal offence for men but not for women. Professional secrecy shall not be binding when it conflicts with the public interest as, for instance, in the case of infectious and venereal diseases. Finally the Congress discussed the question of quackery and unqualified practice and voted for its absolute suppression and for an alteration of the law to this end.

Corrigendum.

On page 6 of the *Indian Medical Year*, 1925, issued as a supplement to last month's issue, a paper on Stibosan in private practice is attributed to K. N. Chatterjee. In place of "K. N. Chatterjee" please read S. K. Das: *vide I.M.G.*, Sept. 1925, p. 425. We very much regret the mistake.—EDITOR, *I.M.G.*

Reviews.

THE NEMATODE PARASITES OF VERTEBRATES.—

By Warrington Yorke, M.D., and P. A. Maplestone, M.D., D.S.O., with a foreword by C. W. Stiles, M.D. London: J. & A. Churchill, 1926. Pp. 536, with 307 illustrations. Price, 36s. net.

THE study of parasitic nematodes has proceeded at an extremely rapid rate in recent years, and it has become increasingly difficult for investigators, particularly those who are interested in systematic phases of the subject (and every parasitologist is and must be to a greater or less extent), to keep abreast of the current literature. What constituted single genera fifty years ago, with no more species than one could count on his fingers, may now be split into as many genera as there were formerly species, and the number of described species has increased many fold. As Dr. Stiles points out in his foreword, the present tendency is to seek knowledge for the sake of the good it will do rather than for the sake of knowledge itself, and it is because of this changed viewpoint that nematology has so greatly expanded. Except in a few of the largest library centres of the world, only a fraction of the literature is ever available, and the worker who is far removed from these centres is greatly restricted in his field and hopelessly handicapped in much research which he might otherwise profitably pursue.

Yorke and Maplestone's book is actually a boiled-down library and museum combined, and makes possible an enormous amount of work in the far corners of the world which otherwise could not have been attempted, and it will be the means of saving countless hours of tedious work for every investigator who interests himself in any phase of the study of nematodes which involves determination of genera. The book makes it possible for anyone with a knowledge of nematode morphology to place correctly any species of nematode which he may come upon in its proper genus, if it belong to any genus described up to the middle of 1925.

The book contains clear and carefully worked out keys to all the superfamilies, families, and genera of parasitic nematodes, the best available description of the genera, the name and synonyms of the type species, and a list of such species as can, with a reasonable degree of certainty, be ascribed to each genus. Of inestimable value are the drawings which illustrate the essential characteristics of each genus. In most cases these are drawings of the type species, but in a few instances the authors have been compelled to use other species for this purpose. A very large number of the illustrations are original, since good illustrations were not formerly in existence; the preparation of these must

have involved a very great amount of work. At the end of the book is a list of 684 references which include the literature which the writers have found of most value for their work, and which will likewise be of most value to the users of the book. The references which deal with any particular genus are listed at the conclusion of the section dealing with that genus.

Works of this kind, on account of the enormous amount of work involved, are usually several years old by the time they appear in print, but by what must have been an almost superhuman effort, the present volume is right up to date and includes, not only in its references but also in its text, work which was published not more than a few months prior to the publication of the book.

To sum up, one could do better than quote the last paragraph of Dr Stiles' foreword, addressed to the "unborn helminthologist": "This work of Yorke and Maplestone was written in order to save your time and mine and to make you more efficient in your professional life. It has cost them many hours and days of patient labour. It has not been prepared in order to gain a reputation. It is a labour of love on their part in order to help you. See that you do for the generation which follows you, what Yorke and Maplestone have done for you."

A. C. C.

OPERATIVE CYSTOSCOPY.—By E. Canny Ryall, F.R.C.S., Senior Surgeon to All Saints Hospital. London: Henry Kimpton, 1925. Pp. xv plus 47, with 115 plates containing 670 original illustrations, of which 528 are coloured. Price, 70s. net.

OPERATIVE cystoscopy was until recently one of the secret arts and hidden mysteries practised only by a few adepts. Its technique was surrounded by difficulties, which could be conquered only by years of work and with the help of abundance of clinical material, such as was obtainable only in the great urological clinics. Little could be learnt by watching such operations, the surgeon with his eye glued to the eye-piece of the cystoscope manipulated his instruments slowly and carefully in the depths of the bladder, each step of the operation being usually followed by sharp hæmorrhage, which necessitated prolonged use of the irrigator before work could be resumed. The intervals of clear vision were much too precious to be wasted in demonstrating what was going on to the spectators. Nowadays all this is changed. The majority of the modern intravesical operative procedures are done by means of the diathermy electrode under local anaesthesia. The work is rapid and clean and there is little hæmorrhage at the time, although the separation of the sloughs some days later may be accompanied by sharp secondary hæmorrhage. Still it is the operator alone who sees what is happening whilst the current is passing, the onlooker must be content with brief peeps during pauses in the operation, and, although these operations are now performed at most general hospitals, only those who are on the staff of a special department as surgeons or as clinical assistants can hope to obtain sufficient practice to acquire a real mastery of the technique. For those who have not this advantage, the work under review will be invaluable. There are several good cystoscopic atlases in French and German and some English translations, but we know of nothing like this work. It contains 115 plates, each consisting of 6 cystoscopic views, perfectly executed in colours. The idea is to show the lesion before treatment and then to illustrate the stages of the electrode approaching it, then the appearance of the tumour during and after fulguration, then its appearance some days later and so on to the end of the treatment. One case of cyst at the neck of the bladder is illustrated by no less than 60 cystoscopic views, drawn during a course of treatment which lasted nearly a year and illustrating the whole process from start to finish. The value of such plates to the learner is beyond question, they are the best possible substitute for the actual personal experience which can be obtained by only a favoured few.

The plates occupy the major portion of the volume, the descriptions of each picture being given in English, French and German, whilst the descriptive letterpress is restricted to some 40 pages, in which the author's methods are briefly described. The opening chapter describes his excellent method of local anaesthesia, cocaine in 0.5 per cent. solution being the agent employed. The next section deals with removal of impacted calculi from the lower end of the ureter, for which difficult operation the author has invented several ingenious instruments. The removal of vesical calculi by means of his own improved cystoscopic lithotrite, which obviates the danger of leaving small fragments behind, is next described followed by a few notes on the removal of foreign bodies from the bladder. The treatment of bladder growths by diathermy is profusely illustrated and it is obvious that the author must have had immense clinical experience. The final sections deal with the treatment of certain types of prostatic obstruction by diathermy and the treatment by intravesical methods of obstruction at the neck of the bladder following prostatectomy, a condition for which a secondary open operation is usually performed. This is controversial ground, but similar methods are now being used in cases of obstruction by fibrous small prostates by a few of the advanced school and there is nothing unsound in its application to post-operative stenosis at the internal meatus, a condition more common than is usually supposed.

We have nothing but praise for this work, which should be of the greatest use to those specialising in this branch of surgery. The author is to be congratulated on his contribution to genito-urinary surgery and and so too is Mr. Thornton Shiells, the artist responsible for the beautiful coloured plates, which are such a unique feature of the work. The price is high, but not unduly so when the immense expense of the production of such a book is considered.

W. L. H.

FRACTURES AND DISLOCATIONS.—By Philip D. Wilson, A.B., M.D., F.A.C.S., and William A. Cochrane, M.B., Ch.B., F.R.C.S. (Edin.). London: J. B. Lippincott, Co. Pp. 789, with 978 illustrations. Price, 45s. net. Obtainable in India from Messrs. Butterworth & Co. (India), Ltd., Calcutta. Price, Rs. 33-12.

A GREAT surgical teacher used to say that a 'dark ooze of base ingratitude' comes out when a bone breaks. Certain it is that the public have very erroneous ideas about fractures. A bone breaks, it is set with a 'click' by the really clever surgeon and healing follows, with the result that the bone is stronger than it was before!

With such views to combat it is obvious that the surgical profession have a public educative duty to perform as well as a duty to their patients.

Good books on fractures and dislocations are rare and the teaching in this branch of surgery in many hospitals is meagre and unpractical, so we more than welcome this excellent volume. The public too, who are beginning to do some medical reading, may learn something from it and be more tolerant of the results obtained in difficult cases.

Perhaps the treatment of fractures by open operation is not sufficiently stressed, but this is better than undue emphasis on methods of plating and wiring, etc. Unskilled surgeons, who after all are very much in the majority, produce woeful results by injudicious selection and imperfect technique. Every case of fracture cannot be treated by orthopaedic experts and it is therefore essential that non-operative methods must be thoroughly taught and in our opinion very good results can be obtained by them.

The treatment of supra-condyloid fractures of the humerus by careful reduction, followed by fixation in full flexion, is favoured in this book. We are quite satisfied that good results can be obtained by this method. Too much impatience is shown by some surgeons in expecting good results in these cases in a

short space of time. Nature, with infinite patience, by moulding and bending can make perfect results which have appeared most dubious. This particularly applies to children, who are most liable to this injury.

'Fractures and Dislocations' is a book which admirably illustrates what can be done by co-operation and team work. A fracture unit would be an asset to every hospital, beneficial to the administration, to the patients and the students.

CLINICAL RESEARCHES IN ACUTE ABDOMINAL DISEASE.—By Zachary Cope, B.A., M.D., M.S. (Lond.), F.R.C.S. (Eng.). London: Humphrey Milford, Oxford University Press. Pp. 148. Price, 12s. 6d. net.

THIS book is a record of clinical researches in acute abdominal diseases, and is both extremely interesting and instructive. It should be in the hands of every surgeon who may be called upon to deal with the "acute abdomen." The chapters on "study of phrenic shoulder-pain" and "subacute perinephric abscess" are of special value. We cordially recommend the book to surgeons in particular.

A SURGICAL CLINICAL HANDBOOK.—By N. S. Narasimham, L.M.P. (Madras), L.C.P.S. (Bombay). Madras: P. Rungachariar & Co., 1925. Pp. 192.

THE purpose of this little book is not obvious. Its value—even as a "cram" book for students is of the slightest; whilst—from the teaching point of view—there is nothing in it which the student will not find in any standard text-book on surgery far better expressed and more helpfully arranged.

INDIAN HYGIENE AND PUBLIC HEALTH.—By C. L. Dunn, D.P.H. (Lond.), Lieut.-Col., I.M.S., and D. D. Pandya, D.P.H. (Camb.), Rai Bahadur. Calcutta: Butterworth & Co. (India), Ltd., 1925. Pp. 679 plus xiv, with 83 illustrations. Price, Rs. 12 net.

THE publishers cannot be congratulated on the get-up of this volume. It is thick and narrow: an awkward shape to hold and severe on binding. The diagrams and illustrations are mostly crude and some of them are really bad.

The illustration of a *Stegomyia* mosquito is a mere smudge, while that of the larvæ of *Culex* and *Anopheles* on page 186 is upside down.

The majority of the work is excellently written in clear and lucid English but with so many good text-books on entomology and protozoology in existence Chapter X might well be modified.

With regard to the Sanitary Law chapter the authors would have done better to write a summary of the Acts after the manner of Robertson and Porter's well known text-book, rather than load the volume with the full text.

There are one or two errors and omissions which the authors should correct in future editions. There is no mention of the work of Leonard Hill and the katar thermometer, and a description of a modern steam disinfectant is wanted. A two-foot head on a newly scraped slow sand filter would give much more than the proper rate of filtration. A two-inch head is possibly meant. In the activated sludge process ripened sludge is mixed with incoming raw sewage, a fact not mentioned here. All the way through borrow pits are called burrow pits.

The book has some excellent standard plans and is bound to be highly popular with health officers in India.

A. B. F.

ALCOHOL IN MEDICAL PRACTICE.—By C. C. Weeks, M.R.C.S., L.R.C.P. London: H. K. Lewis & Co., Ltd., 1925. Pp. x plus 186. Price, 3s. 6d. net.

IN the first chapter the author compares the expenditure on wines and liquors in hospitals in Great Britain and shows that there has been a remarkable decrease in their use during recent years. This the author thinks is mainly due to the increasing disposition of medical practitioners to decrease the use of alcohol in

disease. A large amount of statistical evidence is collected which is to be found in the appendices. In the chapters which follow the author shows that alcohol is not a stimulant, but acts rather as a depressant and narcotic and it impairs resistance to disease. It has a direct toxic action on the myocardium and accentuates cardiac failure rather than counteracts this condition. He deprecates its use in pneumonia, in diseases of children, gastric disorders and surgical conditions. The author is of opinion that the abuse of alcohol has had a disastrous effect on society, and the medical profession should stop its use both on moral and scientific grounds. The chapter on the evolution of medical opinion is interesting and the book is well worth perusal.

WHAT TO DO IN CASES OF POISONING.—By William Murrell, M.D., F.R.C.P. 13th Edition. Revised by P. Hamill, M.D., D.Sc., F.R.C.P. London: H. K. Lewis & Co., Ltd., 1925. Pp. vi plus 276. Price, 4s. 6d. net.

THAT Dr. Murrell's book is well known and popular among medical students and practitioners is evident from the number of editions it has gone through. The thirteenth edition has been thoroughly revised, many new poisons have been added and the subject matter been brought up to date. This little volume is very handy and useful and should be in the possession of every practising physician and senior student.

THE CHEMICAL AND PHYSIOLOGICAL PROPERTIES OF THE INTERNAL SECRETIONS.—By E. C. Dodds, Ph.D., B.Sc., M.B., B.S. and F. Dickens, M.A., Ph.D. London: Humphrey Milford, Oxford University Press. Pp. 214. Price, 8s. 6d.

THE author says in the preface that this book has no claim to originality and is merely a summary of the literature dealing with the chemical aspects of the internal secretions. Nevertheless the book is of great practical utility to those interested in the preparation and standardisation of gland products. The literature on this subject is very vast and scattered and the authors have taken a great deal of trouble in sifting it and presenting to the reader the best methods of isolation and preparation of endocrine substances.

The bibliography at the end of each chapter gives most of the important references and is a useful feature of this book. A summary of the physiological action of the active principles of glands and references to their therapeutic uses enhances the value of this book.

A MANUAL OF CHEMISTRY. VOL. II.—ORGANIC CHEMISTRY.—By A. P. Luff, C.B.E., M.D., B.Sc. (Lond.), F.R.C.P., and H. C. H. Candy, B.A., B.Sc. (Lond.), F.I.C. 7th Edition. London: Cassell & Co., Ltd., 1926. Pp. 268, with 12 illustrations. Price, 6s. net.

A book that has reached its seventh edition within a comparatively short period needs no comment on its merits. It is a worthy successor to its predecessor and will no doubt be useful and popular with those for whom it is intended. There are many valuable additions and a few judicious eliminations which have kept the size of the book very nearly unaltered. By the elimination of such subjects as the method of determination of vapour density the usefulness of this edition has suffered in no way; on the other hand, numerous additions have helped to bring the volume up to date.

The hydrocarbons, alcohols, carbohydrates, glucosides, aldehydes, ketones, organic acids, amino acids, the aromatic compounds, the alkaloids and several other substances of medical interest have been dealt with in a manner specially suited to the needs of medical students. The practical portion of the book not only deals with the preparation of acids and bases and esters but also dwells on the identification of specified organic substances like alcohol, aldehydes, acetone, phenol, acetoacetic acid, cholesterol, alkaloids, etc. Quantitative estimation methods for nitrogen, urea, uric acid, glucose, etc., and the method of finding out the saponification

number and iodine number of fats and oils have also been given in a concise but masterly manner.

The medical student will be pleased with a book which tells him clearly and concisely all he needs to know in order to satisfy his examiner and this book gives all that a medical student is likely to be asked about in organic chemistry.

MUSCULAR ACTIVITY.—By Archibald Vivian Hill, M.A., Sc.D., F.R.S. Baltimore: Williams and Wilkins Co., 1926. Pp. 115. Price, \$2.75.

THIS book consists of four Hertter Memorial Lectures delivered by the author in 1924. The subject matter comprises a series of discussions summarising the most recent researches on the nature of muscular function. The first lecture deals with the dynamics of muscular activity; after discussing various phenomena concerned with stimulation, stretching, viscosity, etc., of muscle, the author says that the cross striations of a muscle are probably there to divide the fibres into water-tight compartments to prevent irreversible segmentation of its contents. The second lecture deals with heat production in muscle. When a muscle is stretched its temperature rises, when it is released the temperature falls. Both these are followed by an irreversible process in which mechanical energy is degraded into heat, owing to the viscosity of the muscle substance. The third lecture deals with the chemical changes in muscular activity and after discussing various processes connected with the formation of lactic acid and its neutralisation, the author says "to pry into the chemical nature of actual process of life is very attractive—but very hard. It is so difficult to get inside the living cell without destroying its structure and stopping its machinery." We have therefore little knowledge of what is actually going on inside a cell and can only speculate. The last lecture deals with the recovery processes after muscular exercise in man and is very instructive.

The book is interesting reading and is well worth perusal.

Annual Reports.

ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH, UNITED PROVINCES OF AGRA AND OUDH, FOR THE YEAR 1924. BY LIEUT.-COL. C. L. DUNN, D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, U. P. ALLAHABAD: SUPDT., GOVT. PRINTING, U. P., 1925. PRICE, RS. 3.

THE question of the introduction of better registration of vital occurrences has been under the consideration of the local government during the year, and a new set of model bye-laws drawn up by the Director of Public Health was circulated. In town areas the duty of reporting such occurrences has now been transferred from the police to the urban authorities. The provincial birth rate for the year was 34.72 as against 36.04 for the previous quinquennium; and the death rate 28.29 as against a corresponding figure of 33.37. As compared with 1923 however the death rate showed an increase under all headings except plague and injuries.

As usual more males were born than females, 112.47 to 100. Municipal areas showed a slightly greater excess of birth over death rates than did rural areas. The highest monthly death rate is recorded in April, 2.78, and the lowest in February, 1.76. The infantile mortality for the year is estimated at 192 per mille, fevers, tetanus and convulsions being the chief contributory causes. Cawnpore returned the enormous infantile death rate of 476.9 per mille, whilst Etawah was a good (? bad) second with a rate of 399.9. The infantile mortality rate was 270.7 in the urban areas as compared with 184.5 in the rural areas. The highest

infantile mortality occurs in October, and the lowest in March.

Of the most important contributory causes to the general mortality, fevers come first with a death rate of 20.9 per mille; cholera second, 1.48; and plague third, 1.24. The total cholera mortality was 67,000 deaths as against 2,591 in the previous year; the districts chiefly affected being Azimgarh, Banda, Jaunpur, Gorakhpur and Sultanpur. The disease was introduced from the adjacent provinces of Bengal and Bihar. In addition to the provision of special allotments to district boards and local bodies, some 12 tons of potassium permanganate were supplied. The special cholera schemes in Almora and on the pilgrim route in Garhwal district were attended with success.

Small-pox shewed 7,224 deaths as against 747 in the previous year, and June shewed the highest incidence of this disease. "Fevers" accounted for 947,807 deaths—or nearly one million. In urban areas the fever mortality was 17.48 as against a figure of 21.13 in rural areas. Malaria, enteric fever, relapsing fever, and—to a very slight extent—kala-azar were responsible, but it is difficult to verify the diagnoses. It is interesting to note that, despite the fact that kala-azar is not to any marked extent a prevalent disease in the U. P. the local government has nevertheless contributed its quota towards the expenses of the Indian Kala-Azar Commission.

Dysentery and diarrhoea accounted for 11,989 deaths, the highest mortality from these causes being in September and the lowest in February. Garhwal for some obscure reason shews a very high incidence, a death rate of 4.18 from these diseases per mille. Respiratory diseases accounted for 27,412 deaths, or a mortality of 0.6 per mille. November is the highest month of incidence and July the lowest.

An interesting table on p. 12 of the report gives the percentages of total deaths from different causes submitted (a) by expert agency, and (b) by unverified, ordinary agency. The differences are very striking; the figures for malaria being 2.1 and 64.2 respectively; for pneumonia 9.4 and 0.4 respectively; for plague 1.2 and 4.4 respectively.

The Assistant Directors of Public Health in the province were Major W. A. Mearns, M.B., D.P.H., I.M.S.; Captain D. Clyde, M.B., D.P.H., I.M.S.; Dr. A. Sousa, D.P.H.; and Dr. K. P. Mathur. Major J. A. S. Phillips, D.P.H., I.M.S., was Assistant Director of Public Health (Malariology). A special class for fifteen medical officers was held in malariology at Banbassa. As in previous years the work at Banbassa (the headquarters of the great Sarda Canal construction) was arduous and exceedingly successful. Since the malarial branch in the province commenced work at Banbassa the annual period during which work is carried on has been lengthened by two months as the result of anti-malarial measures. The monsoon in 1924 was late and was a heavy one, and extensive jungle clearing had in consequence to be undertaken. This was followed by an extension of the drainage and new swamps not previously dealt with were attended to. During the working season quinine prophylaxis was systematically carried out and the results appear to have been very good. A branch dispensary was opened in the main labour camp. At Saharanpur the results of previous measures have been exceedingly successful in reducing the malaria rate, but Major Phillips reports that reopening of the small irrigation canals and their neglect threatens to undo all the good accomplished. A total of Rs. 14,202 worth of quinine was sold through the different agencies, as against a corresponding amount of Rs. 7,784 in the previous year.

The total number of deaths from plague in the British districts was 56,210 as against 74,187 for the previous year. Meerut, Bulandshahr, Azimgarh, Ghazipur and Muttra were the districts most heavily infected. A total number of 45,430 persons were inoculated with anti-plague vaccine during the year. When properly organised and supervised, evacuation of the infected dwellings

is a most useful measure. There were 36 travelling dispensaries at work during the year, and they have been so successful that they have now been made a permanent institution in the public health policy of the province. In addition, further provision was made for maintaining at district headquarters demobilised travelling dispensaries, with equipment, etc., all held in reserve, which can be mobilised on the appearance of any epidemic.

The Publicity Bureau was in charge of Dr. Khalil-ul Rahman, and a large volume of propaganda work was carried out. There are now 38 complete sets of lantern equipment, 10 sets of posters and booklets, and 38 sets of lantern slides. It is a pity that the contribution from local bodies towards this work is so little, amounting in 1924 to only Rs. 5,400. The district health scheme was extended to the districts of Fyzabad and Gonda, and is now in force in all five districts. The chief duties of the officers appointed under these schemes is the control of epidemic plague and cholera, supervision of vaccination, hygiene propaganda, routine inspection of villages and schools, and verification of vital statistics. Each district scheme includes a district medical officer of health, an assistant medical officer of health, a sanitary inspector, a travelling dispensary with personnel and equipment, and vaccination staff. The organisation is as yet only a skeleton one; but it provides a nucleus for expansion when severe epidemics set in; and a permanent health staff for general control of rural public health and has proved of great utility.

Turning to more general matters, 3 out of 10 municipal boards which had not appointed municipal medical officers of health, as a result of official pressure, were induced to appoint such officers during the year. Where such officers are installed they prove so useful that it has proved very difficult to secure their absence for even so short a time as to attend the classes in malariology at Banbassa. The conditions of service of these officers, however, need improvement. The provisions of the Food Adulteration Act were extended, and much work done in the Public Analyst's department. Eighty-eight persons were prosecuted under this Act during the year, of whom 67 were fined, the total fines amounting to Rs. 1,153. Child welfare and maternity propaganda are being steadily pushed throughout the province; at Allahabad there are two centres, and 1,194 labour cases were attended, and 11,505 visits to homes paid. At Bareilly 1,327 labour cases were attended by the staff of Mrs. Stubbs' Maternity and Child Welfare Society. At Gonda a maternity ward has been built at Nawabganj, and at Dehra Dun a new centre has been opened; whilst other centres in the province continued to do good work during the year. Hitherto the policy with regard to the training of *dhais* has been to train as many as possible; it is now felt that efforts should be made to secure a better class of *dhai* for training, and a two years' course of training, either at a hospital or at a centre for maternity and child welfare is suggested. In all 46 probationer midwives were in training during the year under the All-India Lady Chelmsford's League, of whom 11 passed out.

Grants totalling Rs. 7,21,945 were sanctioned by the Board of Public Health during the year. Colonel Dunn draws attention to the fact that—apart from provision for vaccination,—there are very few district boards which spend any appreciable sum of money on hygiene and sanitation. On the one hand large grants are made by the provincial governments; on the other hand, the *ma bap* policy is adopted, in the hope that Heaven will provide, or that epidemics may not arise. "I am strongly of opinion that, while it is the duty of Government to assist local bodies by supplying superior expert personnel to organise and control public health measures in districts, it is undoubtedly the duty of local bodies to furnish funds for inferior personnel, hygienic measures and sanitary improvements. The percentage of the total income of the district boards devoted to these purposes is infinitesimal, whereas in municipal boards a large proportion of the municipal income is

spent on the improvement of public health. . . . The district boards have at present no organisation for expending such grants. This organisation, however, is gradually being provided by the extension of the district health scheme."

The many fairs and festival gatherings in the province passed off successfully during the year without the outbreak of epidemic disease, and advantage was taken of these fairs to give lantern lectures and carry out hygiene propaganda. During September and October extensive floods occurred in certain parts of the province and the Public Health Department took its share in the relief measures; travelling dispensaries were specially mobilised and quinine to the value of Rs. 7,000 distributed, whilst advantage was taken of the destruction of villages to advise reconstruction on approved sanitary lines.

Colonel Dunn's report is perhaps chiefly of interest in connection with the introduction of the public health scheme for districts. The report also includes the annual report of the Superintending Engineer, Public Health Department, U. P. for the year,—Mr. G. McC. Hoey, M.Inst.C.E.

ANNUAL STATEMENTS OF THE DISPENSARIES AND CHARITABLE INSTITUTIONS OF THE PUNJAB FOR THE YEAR 1924. By LIEUT.-COL. G. TATE, OFFG. I.G.C.H., PUNJAB, LAHORE: SUPDT., PUNJAB GOVT. PRESS, 1925. PRICE, RS. 3.

THE year opened with 626 hospitals and dispensaries of all classes, and closed with 640. The number of local fund institutions continues to increase steadily and has risen from 312 in 1920 to 371 in 1924. There were 31 travelling dispensaries in operation at the close of the year, and Colonel Tate speaks well of their activities. The official ideal of one dispensary for every 100 square miles of country has yet not come within sight however; excluding special female police, canal, etc., dispensaries there is on an average one general dispensary to every 287 square miles, with an average population of 62,643. The local bodies appear to have reached the end of their resources, and further expansion can only be expected if funds are provided by the provincial government. The matter however is under the consideration of the Punjab Government and it was hoped in 1925 to start 70 new dispensaries, these dispensaries to be in charge of sub-assistant surgeons recruited by district boards on a five-year contract basis.

The total number of patients treated during the year was 5,935,079 and included in-patients numbering 109,503,—figures which almost stagger the imagination, but which shew at least that medical relief is a reality in India. We have heard so much lately about the Indian masses who are never reached by present-day modern medicine that it is just as well that the other side of the picture should be presented. An average number of 5,532 beds was occupied by an average daily number of 3,931 patients. An increase of some 300,000 in the out-patient attendance for the province is ascribed to epidemic malaria in certain parts of the Punjab during the year. Cholera and small-pox also shewed a definite increase during the year. No less than 1,372,675 persons suffering from eye troubles were treated. Surgical operations numbered 292,026 during the year; cataract operations numbering 18,778 and litholapaxies 1,317. At Moga the work of Rai Bahadur Dr. Mathra Das is not merely provincial, but attracts patients from all over India.

The total income for this enormous provision of medical relief throughout the province was Rs. 43,43,450. It is gratifying to note that there has been a substantial increase in the subscriptions from Indians, a total of Rs. 1,46,735 as against Rs. 51,947 in the previous year being recorded. Several instances are quoted of considerable sums being collected for specified purposes by different doctors and other public spirited individuals of the community. Expenditure during the year amount-

ed to Rs. 42,06,627. At the Maternity Hospital, Lahore, the experiment was tried of allowing students to attend and conduct labour cases; to some extent the patients concerned left hospital in consequence, but, on the whole the experiment was successful. It is the first time that such an experiment has been tried in the Punjab.

The most notable feature of the year was the opening at Simla of the Lady Reading Hospital for Women and Children. A separate female hospital has also been provided at Dera Ghazi Khan. The work of the Punjab Medical School for Women at Ludhiana has steadily increased, and there were 33 new students enrolled during the year, of the female sub-assistant surgeon class. The supply of female dispensers is still inadequate, but it is hoped that the lowering of the standard of academic qualifications required—previously almost the same as for entrants to the sub-assistant surgeon class—will improve the supply. The number of trained *dhais* in the province was held to be insufficient to warrant the introduction of their compulsory registration.

The post of Lady Assistant to the I.G.C.H., Punjab was abolished early in 1925, Dr. D. F. Curjel Wilson having retired. Special provision was made at the King Edward Medical College, Lahore, for research work into Indian indigenous drugs. Measures were taken to prevent patients attending hospital being victimised by the subordinate hospital establishment, and notices forbidding the taking of gratuities by such establishment were posted in prominent places in hospitals and dispensaries.

Colonel (now Major-General) R. Heard, C.I.E., K.H.S., I.M.S., was in charge for the first three months of the year; Lieut.-Col. E. L. Ward, C.B.E., I.M.S. subsequently; and Colonel C. R. Bakhle, I.M.S. with effect from the 4th June 1924.

The "Annual Statement" together with its annexed tables may appear to be a somewhat uninteresting document. In reality it represents an enormous field of active medical and surgical work, and shows how much is already being done for the rural population of India, under government and official aegis.

ANNUAL REPORT ON THE CIVIL HOSPITALS AND DISPENSARIES, MADRAS PRESIDENCY FOR THE YEAR 1924. BY MAJOR-GENERAL T. H. SYMONS, C.S.I., O.B.E., K.H.S., I.M.S., SURGEON-GENERAL WITH THE GOVERNMENT OF MADRAS. MADRAS: SUPDT., GOVT. PRINTING, 1925. PRICE, RS. 2-6-0.

THE number of medical institutions in the province was 766, in addition to which several local bodies are being subsidised by government under the scheme for extending medical aid in rural areas; 58 rural dispensaries have been sanctioned in *taluk* board areas and many more are likely to be opened. In-patients during the year numbered 145,651, and out-patients 8,502,474; the death rate among in-patients was 4.83. The chief diseases among in-patients were in order of frequency malaria, disorders of the digestive system, of the skin, and of the respiratory system; among out-patients eye diseases were a conspicuous feature of the work. Of the total number of in-patients and out-patients treated, 6,580,930 were Hindus, 1,029,945 Mahomedans, and 53,048 Europeans and Anglo-Indians. Operative work during the year shewed an increase notably in aural, mastoid and eye operations. Financially the total income during the year was Rs. 56,94,216, of which the provincial government contribution was Rs. 31,13,529.

A total of 27,291 persons were examined for hook-worm infection, and 64 per cent. were found to be infected; 123,095 treatments were given, thymol, cheno-podium and carbon tetrachloride being the drugs chiefly used. Small-pox cases treated numbered 1,111 with only 90 deaths—a very satisfactory figure. Of labour cases 49,115 were attended by 493 midwives. The system of appointing suitable private practitioners as honorary

physicians and surgeons to the Presidency State hospitals in Madras is reported to be working smoothly. The year was especially noteworthy in the *extension of medical relief in rural areas by subsidising private medical practitioners*. "This has not only solved the problem of bringing medical relief of the best kind within easy reach of the rural population," writes General Symons, "but it has also solved the problem of unemployment of medical practitioners. By this system these practitioners are granted subsidies or honoraria and provided with medicines also if they agree to settle down in specified villages. An additional subsidy is given to such of the medical men as engage and maintain a qualified midwife. Fifty-eight such dispensaries were sanctioned for opening during 1924." The scheme is a very interesting one as it represents a real attempt to solve this paramount Indian medical problem.

A special retrenchment officer was appointed by government during the year to inspect the Presidency State hospitals in Madras city and some headquarter hospitals; and, as a result of his recommendations, certain appointments have been abolished and the maximum cost of diets fixed.

The district medical libraries had 695 members on their lists during the year.

ANNUAL RETURNS OF THE HOSPITALS AND DISPENSARIES IN BIHAR AND ORISSA FOR THE YEAR 1924. BY LIEUT.-COL. J. MASSON, M.B., F.R.C.S.E., I.M.S., OFFG. I.G.C.H., BIHAR AND ORISSA. PATNA: SUPDT., GOVT., PRINTING, BIHAR AND ORISSA, 1925. PRICE, RS. 3-2-0.

THE year opened with 546 and closed with 580 hospitals and dispensaries of all classes. The total number of patients treated was 4,102,732 and shewed an increase of over half a million on the figure for 1923. There was a decrease in the numbers attending the travelling dispensaries, however, as some of these were closed down during the year. Hindus treated numbered 3,183,463; Mahomedans 825,112; and Europeans and Anglo-Indians 6,757.

The year on the whole was not so healthy as was 1923, and the death rate among the general population rose from 25 per mille in the previous year to 29.10, the increase being chiefly due to epidemic cholera and small-pox. There were 25,435 cases of cholera treated at dispensaries and hospitals in 1924 as against 3,697 in 1923, but it is noted that the number of deaths which occurred among these cases—344—was actually less than in 1923, when it was 315. (It is doubtful however whether this death rate for 1924 is correct, for in Statement C in the report one notes figures of 22,400 and 240 out-patients treated for cholera with no deaths at all shewn). For in-patients the figures shew a mortality of from 10 to 20 per cent. for different classes of institutions.

Plague was unimportant during the year, and accounted only for a general mortality of 0.3 per mille. The number of small-pox cases treated shewed a marked increase on the 1923 figures; 675 as against 407. Malaria also shewed a definite increase. In connection with influenza, vaccine was supplied by government free of cost to all civil surgeons and jail superintendents. A grant of Rs. 1,200 was also, as usual, given for the purchase of arsenical compounds for the treatment of syphilis in *sadr* hospitals and subdivisional hospitals where an assistant surgeon is employed. No less than 28,669 patients with kala-azar were treated during the year; and Colonel Masson writes that the introduction of urea-stibamine is being arranged for. The scheme for establishing a tuberculosis sanatorium at Sabour has been abandoned, as the place was not considered suitable; instead an annual grant of Rs. 1,500 has been sanctioned to the King Edward Sanatorium, Dharmapore, Simla Hills, to reserve one bed for a non-paying patient from the province. A scheme for the establishment of a sanatorium at Ranchi is under consideration. During the year pulmonary tuberculosis cases treated numbered

10,333, an increase of nearly 2,000 on the previous year. The Filariasis Hospital at Puri is doing splendid work, and its activities have now been extended to investigations in connection with ankylostomiasis and Strongyloides infection,—which latter is stated to be fairly common and possibly responsible for the poor physique of the Oriya. Additional facilities have been provided for the treatment of leprosy at *sadr* and subdivisional hospitals, and there were nine asylums at work in the province during the year.

Surgical operations reached a total of 249,507 with 378 deaths. Financially, the total income during the year was Rs. 24,54,561 and the expenditure Rs. 24,20,045. The maternity welfare scheme at Patna under the supervision of Mrs. Duncan White has been working satisfactorily and a new infant welfare centre there was started under a grant from the Lady Dufferin Fund. A similar scheme at Cuttack under the auspices of the Red Cross Society is also doing good work. In order to increase the supply of "Electrolytic Chlorine" and make it available all over the province, the plant at Pusa was enlarged and it is proposed to establish plants at Patna, Ranchi and Cuttack, these centres to be under the supervision of a specially trained chemical assistant.

The work of the Radium Institute at Ranchi has recently been commented on in our columns, and in 1924 the number of patients treated was 253 as against 189 in the previous year. The Temple Medical School at Patna has been closed and a new medical school opened at Darbhanga; the buildings and equipment for the new Medical College at Patna were almost ready and this institution has since been opened as the Prince of Wales' Medical College.

At the hospitals situated at headquarters of subdivisions in the province sub-assistant surgeons are being replaced by assistant surgeons, under a scheme sanctioned by government in 1923.

ANNUAL ADMINISTRATION REPORT OF THE ASANSOL MINES BOARD OF HEALTH FOR THE YEAR 1924-25.

THIS report is in the nature of a compilation in six parts. Part I deals with the composition of the Board, its staff and establishment, its financial powers and engineering matters; Part II, by Dr. J. W. Tomb, O.B.E., M.A., M.D., D.P.H., Chief Sanitary Officer to the Board, is the administrative report of the year; whilst the remaining parts are taken up by copies of the Bengal Act of 1912 (Bengal Mining Settlements' Act of 1912, as modified up to the 1st October 1915) and *Regulations for the Prevention and Control of Cholera in the Asansol Mining Settlement*. In the appendix to the report a series of interesting plans shew a sanitary well parapet, a model bathing ghat, and standard specifications and plans for model dwellings, *dhowrahs* and isolation huts. This last section will especially appeal to public health officers faced with the question of isolation of cases of contagious disease. In Part I we regret to see that the number of letters received during the year was 1,637 and the number issued 3,033, but we suppose that so large a volume of official correspondence is inevitable in India in connection with so large an undertaking as this Board of Health. The disease to which a correspondent of this journal has called attention—*taniasis rubra* (infection with the "red tape" worm), is universal in this country.

Turning to Part II, which concerns us chiefly, an account is first given by Dr. Tomb of the public health organisation of the district, largely taken from his article in our issue for April, 1925, p. 156. The Settlement includes 263 collieries, 490 villages, the two municipalities of Asansol and Raniganj, and a total population—according to the census of 1921—of 329,356. The chief epidemic diseases are cholera and small-pox, plague being unknown in epidemic form. In 1924-25 there were 444 cases of cholera with 273 deaths—a case mortality of 61.5 per cent., but of 6,364 contacts who took the "essential oils" mixture, not one developed cholera, and no second case of cholera occurred in any infected house in the

Settlement. Of 72 cases treated with the same mixture before the stage of collapse set in, 96 per cent. recovered. Small-pox accounted for 202 cases with 28 deaths; of whom 72 patients were unprotected by vaccination, and of these 15 died. The death rate in the remaining protected 130 cases was 13 or 10 per cent. Primary vaccinations during the year numbered 16,634 and secondary vaccinations 16,825 respectively.

In general, vaccination is afforded free of cost and the attitude of the population towards vaccination is in general friendly, except in the Marwari community in Ranigunj where resort had to be made to legal measures of compulsion.

The general birth rate for the year was 26.02 per mille and the death rate 18.53; for the past five years the number of births has consistently exceeded the number of deaths. As contributory factors to the death rate, respiratory diseases come first, then fevers, cholera, dysentery and diarrhoea. Infant mortality was 138 per thousand recorded births, a figure which compares favourably with those for any other areas in India. "This low infant mortality can only be attributed to the satisfactory hygienic conditions maintained in the Settlement by the activities of the Mines' Board." The death rate in childbirth amongst adult married women was 4.4 per 1,000 births; amongst several hundred deliveries attended by the Board's midwives during the year there was not a single maternal death.

Malarial survey work was continued during the year. Five further wells of special protected type were provided during the year; and the 2,157 children at 89 schools inspected. Lectures and propaganda work are steadily carried on, and five baby shows were held in the Settlement during February and March. In general it is to be noted that the relations between the public health staff and the general public were very friendly and no opposition to measures was encountered anywhere. The erection of proper dwellings, *dhawrahs*, and isolation huts was steadily pushed during the year and the supervision of shops duly attended to.

In the concluding sections of the report the details of the Bengal Mining Settlements' Act of 1912 well deserve study by sanitarians in India, since the powers given appear to be considerably greater than those usually in force in other non-specified areas, with corresponding benefit to the population concerned.

ANNUAL REPORT ON THE MEDICAL AND HEALTH DEPARTMENT, MAURITIUS, 1924.

The population of Mauritius was 387,743 in December 31st 1924. The birth rate has shown a steady increase during the last five years and is now 40.4 per thousand.

The death rate is showing a steady decline and is now 27.7 against 40.33 for the preceding quinquennial period. The highest death rate was in July, as was the case last year; this was due to influenza.

Malaria claims the most victims again this year but the death rate from this infection is declining and in Port Louis, where energetic measures have been taken, it has declined by steady stages from 518 deaths in 1919 to 120 in 1924.

Infantile mortality is again high but is also showing a marked decline being now 129.6 per thousand births.

Midwifery and Child Welfare: The scheme under this heading is mainly supported by bequests and voluntary contributions but is also aided by Government grants.

Two crèches exist for taking in infants deprived of good food and proper care; two other crèches for looking after infants during the day while the mothers are at work.

A scheme for the training of midwives has been in existence for some years; these midwives are distributed throughout the colony. A difficulty about the employment of these midwives [which is also the difficulty in India] arises; the people prefer the old-fashioned unqualified midwife who works for much less remuneration and will also turn her hand to household

duties such as washing linen, while the mother is in bed. The next problem is to persuade the people to employ the qualified midwives. There are 518 unqualified persons who admit to practising midwifery, the actual number that do practice it is probably much greater.

Two nurses have been appointed to undergo special training as health visitors.

Plague: This disease was first observed in 1899 when 1,416 cases and 1,117 deaths were reported. The disease has undergone a more or less steady decline down to the year 1918 when no cases were reported. Cases were again observed in 1921. In 1924, 161 cases and 144 deaths have been reported, this shows a high death rate, almost 90 per cent.

During the year 83,263 rats were destroyed, of those examined just over 1 per cent. were found to be plague infected.

Failure to eradicate plague and incomplete success of the anti-rat campaign are attributable to the following causes:—

(i) Lack of co-operation on the part of the vast majority of the community, due mostly to ignorance, apathy and scepticism.

(ii) Defective housing conditions.

(iii) Overcrowding in small, ill-ventilated rooms and insanitary mode of living of the general mass of the population.

(iv) Non-rat-proof grain stores. In addition to the grain stores proper, every Chinaman's shop is an actual grain store.

Rice, other grain and gunny bags are stored all over the town in non-rat-proof buildings.

The remedies suggested are:—

(i) Educational propaganda.

(a) The teaching of hygiene in primary schools and girls' secondary schools which was started several years ago has not shown its beneficial effects fully yet, but it is only gradually that these effects may be expected to be materialized. The teachers after having personally derived the fullest benefit from the lectures of the public health officer, should take to heart the imparting of the elementary principles of hygiene to the schoolboys and girls. At the same time, hygiene should be taught in all schools and colleges without exception.

(b) Cinema films, lectures, illustrated leaflets and posters.

Several cinema films and a complete portable projection (electric power) apparatus have been received. The titles of the films which have already been received are: "Mosquitoes and Malaria," "Swat that fly," "The Rat Menace" and "Ankylostomiasis." The films have been shown free of charge in schools and elsewhere and free open air exhibitions will also be given.

Several leaflets (bulletins) have already been published in English and French and on occasion arising this procedure will be continued.

(c) It is expected that with the complete and efficient training the sanitary staff is now undergoing, sanitary officers will be conscious of and alive to the educational mission they are entrusted with towards the community as regards all the aspects of public health.

(ii) and (iii) More houses, better housing conditions and domestic hygiene.

Of enteric fever, 107 cases were notified; this is the lowest figure yet recorded.

A wave of diphtheria swept over the districts of Plaines Wilhem and Moka; 2/3rds of the total number of cases occurring during the months of October, November and December. No cases of small-pox were reported. Altogether 10,944 children were vaccinated; 10,429 were reported as successful at first attendance.

Malaria: Routine examination of the blood of school children was undertaken to ascertain the infection rate. Out of 6,884 children examined 378 or 5.4 per cent. were found to be infected.

Leprosy is not a notifiable disease. There are only 38 inmates in the leper asylum.

It is probably common enough in the colony. Every day cases are met with in the streets of Port Louis and elsewhere.

No law exists for the compulsory segregation of lepers except convict, pauper or vagrant lepers. They wander about at liberty living with their families and transmitting the disease.

There is no power to prohibit marriages between or with lepers, hence the taint continues to be spread.

In the draft Public Health Ordinance leprosy is made notifiable and power is given to the Director of the Health Department to make regulations providing for the restriction of lepers in regard to various trades and occupations. It is hoped that this ordinance will soon be passed and put into force.

Pulmonary Tuberculosis.—This disease is not notifiable yet in Mauritius. Provision for its compulsory notification has been made in the draft Health Ordinance.

The mortality due to pulmonary tuberculosis represents 8.2 per cent. of the total deaths for 1924 against 7.7 per cent. in 1923. The months with highest deaths were November (94), August (91), October (88), and those with lowest deaths, January (49) and February (48).

Ankylostomiasis.—During the year under consideration the hookworm campaign, carried on by the International Health Board of the Rockefeller Foundation on a three years' agreement started in May 1922, examined a total of 42,085 persons in the four districts where soil sanitation had been completed, viz. Port Louis, Moka, Grand Port and Savanne. The findings are shown in the table hereunder:

SUMMARY OF HOOKWORM CAMPAIGN—1924.

District.	Census.	Examined.	POSITIVE FOR					
			Hookworm.	OTHER HELMINTHS.				
				Ascaris.	Trichocephalus.	Strongyloides.	Oxyuris.	Tœnia.
Port Louis	3,551	2,838	1,492	1,248	2,469	6	12	..
Moka	7,226	5,509	4,506	3,087	2,539	30	15	1
Grand Port	36,748	25,136	18,855	13,198	11,640	9	7	..
Savanne	12,573	8,602	6,856	4,693	3,228	6	44	..
Total	60,098	42,085	31,709	22,226	19,876	51	78	1

Water-Supply.—The water-supply of Port Louis is derived from Grand River North West and Bathurst Canal. Government establishments and some private firms and buildings are provided with Mare-aux-Vacoas water. The first two supplies of water are unfit and unsafe. It is hoped that the chlorination plant under erection at Pailles, in the bed of Grand River N. W. will soon start working and that filtered chlorinated water will be substituted for the crude, impure water that 95 per cent. of the inhabitants of Port Louis are obliged to consume.

The fact that the water-supply is a most important factor towards the health of a community is now almost universally realized in Mauritius. The various District Boards have taken the question in hand and the water supplies of country districts are being largely improved and extended, mostly by piped supplies from pure sources or unpolluted springs and rivers.

Milk.—During the year the Director, Medical and Health Department, submitted to Government a comprehensive scheme with accompanying regulations dealing with the control of conditions in which milk is and should be produced and sold.

These regulations necessitating proper structural conditions could not be dealt with under present building regulations and a bill has been prepared giving the sanitary authority power to deal with buildings. It is hoped that in the near future this bill will become an accomplished fact.

Little or no attempt to secure radical structural improvement of byres has been accomplished. The existing byres are unhealthy, overcrowded and badly ventilated.

Paris Green as a Larvicide for Anophelines.—This dye has been tried to a small extent in Port Louis with very good results. In the first experiment the dye was diluted with street dust in the proportion of 1 part Paris green (by measure) to 9 parts street dust. A small barachois 30 feet long, 10 feet broad and about 1 foot average depth, in the estuary of the St. Louis river was used for the first trial. This pool was one of a pair which contained quantities of green alga growing in the brackish water. The pool was inhabited by small fish, water snails, agnionid larvæ and larvæ of *Anopheles costalis*. The mixture of dye and dust was thrown by hand on the surface of the water until the whole surface had been covered with a fine green scum.

At the end of 30 minutes trial dips were made and living *costalis* larvæ were obtained. These were taken back to the laboratory and transferred to clean water. They all died during the course of the afternoon. Larvæ from the control pool a few yards distant from the experimental pool, collected and kept in the laboratory under the same conditions, were alive the following morning.

The pool was revisited 23 hours after the application of the dye. The following note describes the conditions met with:—"Water clear and limpid. Large numbers of small stunned snails present. Fish stupe-

fied and easy to catch but no dead fish seen; 20 dead *costalis* larvæ recovered. No living larvæ found. Larvæ of agnionidæ alive. Larvæ in control pool healthy." Subsequent visits showed recovery of snails and fish.

Later, collections of surface water which had been found to contain *A. costalis* larvæ were treated with a mixture of Paris green and dry sawdust, the dye being mixed with the sawdust in a strength of 5 per cent. by volume. The larvæ were all killed.

It was noted that in some of the pools in which anopheline and culicine larvæ occurred together, the anopheline larvæ were sometimes the only ones to be killed by the application of the dye. In this connection the following note describes an observation made one evening:—

"May 16th.—*A. costalis*, *mauritanus*, *funestus* and *Stegomyia* larvæ placed in some water. Control batch put aside. Larvæ observed. Feeding well. Anophelines lie on surface of water and feed by rotating head through an angle of 180° and sweeping the surface of the water with their brushes from below. If water shallow enough they may feed on bottom. Lie at rest quietly feeding. *Stegomyia* very active, feeding mainly

on bottom of dish and sometimes in mid-water. Do not often sweep surface.

"5-30 p.m.—Paris green dusted on water.

"Anopheline larvæ ate much greater quantities of floating Paris green than *Stegomyia* did. Anopheline larvæ appeared to become paralysed. At 10.30 p.m. the anophelines were still alive, but very sluggish in their movements, the *Stegomyia* larvæ were apparently unaffected.

"By morning all the larvæ and one cyclops were dead. One pupa was alive after 24 hours and subsequently hatched. The control batch were normal."

It would appear that the apparently selective action of the dye is due to the different feeding habits of the larvæ.

The surface feeders absorb a much greater quantity of the substance than the bottom feeders, and suffer accordingly. This is also the probable explanation why fish and other aquatic creatures are immune to quantities of the poison which are fatal for anophelines.

Further observations will be reported in due course.

Markets.—The markets and abattoir of Port Louis were frequently inspected by the sanitary authority during the year. No steps were taken by the municipality to remedy the structural defects of these places or to instal satisfactory appliances and fittings; 435 unclaimed dogs, captured by the police in the markets as strays, were destroyed in a humane manner.

In spite of the activity shown by the police there are still too many uncontrolled dogs roaming at large in the town.

In the extra urban areas 57 stray pigs were shot by the police.

Tuberculosis in cattle at Plains Wilhems.—A large number of cattle have been found to be tuberculous when slaughtered in the Rose Hill abattoir. Accordingly the Director of Agriculture is organizing a campaign in the district to extend the information thus obtained, whereby the tuberculin test is to be applied section by section in the district. It is suspected that the stall accommodation provided by private owners is insufficient.

Training of Staff.—Classes of instruction have been held for Sanitary Inspectors and Guards, in which the Drainage Engineer has assisted.

Mahébourg has an open market which is utilised practically twice a week by occasional sellers for some 3 or 4 hours at a time.

In all three districts meat is sold in specially approved shops—control if difficult is still possible. Not so much can be said in respect of fish which is hawked in baskets, and of vegetables which continue to be exposed for sale on tablets under the verandahs of Chinamen's shops where they receive dust from the street. A few years ago an article in the building law was introduced which did away with the possibility of using open verandahs along high roads for the purpose. Unfortunately upon representations received from interested quarters a return to the old objectionable system was rapidly made.

The ratio of insane to total population is 17.69 per 10,000. It is interesting to compare this rate with the average total insane rate for European countries which is 40 per 10,000; that for England and Wales, as given by the Board of Control for the year 1923 being 34.40 per 10,000 of population.

The chief reasons for this marked difference between the Mauritian and European total insane rates seem to be: (a) the more acute struggle for life in Europe and the consequent increased worry, anxiety and privation; (b) the much greater prevalence of general paralysis of the insane in Europe, where 15 to 20 per cent. of all admissions into mental hospitals suffer from this disease. Another reason may be that a higher standard of sanity is demanded in Europe. In Mauritius, although syphilization and civilization are both advanced, general paralysis is practically non-existent.

(ii) The insane rate for Creoles was 34.51 per

10,000, that for Indians and Chinese being 10.92 and 17.79 respectively.

The insane rate for Creoles is, therefore, more than three times that for Indians. It would appear that the greater prevalence of insanity among Creoles is accounted for by the fact that the Creole is, as a rule, more highly strung than the Indian and is, therefore, more prone to succumb to psychic trauma than the more phlegmatic and fatalistic Indian. Again, unemployment is more rife among Creoles who, as a class, shew a natural aversion to agricultural work, hence worry and privations are more frequent ætiological factors in the causation of insanity among them.

(iii) The male insane rate for all classes was 19.53 per 10,000 and the female rate 15.72.

Contrary to what happens in most countries the male insane rate in this Colony is higher than the female rate.

ANNUAL CLINICAL REPORT OF THE GOVERNMENT HOSPITAL FOR WOMEN AND CHILDREN, MADRAS FOR THE YEAR 1924. BY LIEUT.-COL. C. A. F. HINGSTON, C.I.E., O.B.E., I.M.S. MADRAS: SUPDT., GOVT. PRINTING, 1925.

This report shews in statistical form the enormous volume of work carried out by this celebrated hospital and teaching school. Colonel Hingston was in charge until July, when he proceeded on leave, and Major W. C. Gray, I.M.S., replaced him during the rest of the year.

Obstetric cases numbered 2,981, and gynecological cases (including diseases of pregnancy), 3,644. There were in all only 67 deaths amongst 2,908 patients delivered during the year; including 4 cases of eclampsia, 13 of puerperal septicæmia, and 24 of non-puerperal origin.

In all 38 cases of eclampsia were treated during the year, of whom the 4 mentioned previously died; of these 38 cases in 22 birth was by natural powers; in 12 cases forceps were used, and once Cæsarean section had to be resorted to; 22 of the patients were primiparæ, and 16 multiparæ; 40 children were born, but only 17 of them living. A detailed and most interesting table gives full particulars of these cases.

Turning to the total 2,908 deliveries recorded,—which number is arrived at by excluding patients delivered on the way to hospital, or elsewhere, etc.—1,801 had natural and not prolonged delivery; 414 had difficult delivery; 107 preter-natural delivery; 460 were complex cases; and 126 cases of abortion. One patient gave birth to quadruplets; in 10 cases there was rupture of the uterus; whilst the chief incidence of abortion—22 out of 42 cases treated—was in "pyrexia of uncertain origin." The obstetric operations carried out numbered in all 999, and included 372 instances of application of forceps; 64 of podalic version and extraction; 22 Cæsarean sections; 13 of morbidly adherent placenta; and 377 of immediate suture of the perineum.

The ratio of different classes of patients admitted is shewn in the following figures:—Europeans and Anglo-Indians, 291; Hindus, 1,163; Mahomedans, 65; which well illustrates the unwillingness of the Mahomedan community to avail themselves of the facilities provided by the hospital.

Of the 2,908 deliveries, 2,544 were vertex presentations, and 89 breech or foot, whilst 47 were cases of plural births. No less than 2,211 went to full term, but 694 were premature or aborted.

Of 1,801 cases of natural labour lasting less than 24 hours, the percentage of primiparæ was 23.15, with an average duration of 12.37 hours as against one of 7.81 for multiparæ. In the class of difficult labour, with presentation of the head, face or brow, in 346 deliveries by forceps the maternal mortality was 2.6 per cent., whilst 2 out of 17 cases of Cæsarean section died. Of preter-natural labours there were 107 cases, mostly of breech presentation, where one or more parts of the body presented; no less than 65 of these patients were delivered by natural powers. Complex labour included

chiefly cases of plural births, eclampsia, post-partum hæmorrhage, placenta previa, descent of the funis, and adherent placenta, or disease of the decidua or ovum. With regard to plural births, there were 97 children born in 47 labours,—all twins, with the exception of one case of triplets and one of quadruplets. Of these 97 children, 59 were born alive, and 35 mothers were delivered by natural powers.

Of the total 2,832 babies born during the year, as the result of 2,782 deliveries (excluding 126 abortions), 2,261 or 91 per cent. were of full term, and 571 premature. Of indications for different obstetric operations, podalic version with extraction was chiefly called for in cases of the foetal head not being fixed, transverse presentations, and cases of prolapse of the cord: podalic version was called for in 34 cases of breech or foot presentation: forceps were called for chiefly in connection with maternal or foetal distress—287 out of 372 instances—; for persistent occipito-posterior presentations, for cases with the cord around the neck, and in cases of eclampsia. The proportion of live births in forceps cases was 92.5 per cent.,—a most satisfactory figure. Caesarean section, 22 cases, was chiefly indicated in cases of previous Caesarean section, generally contracted pelvis, and complex pregnancy. 17 out of 22 mothers survived, and 15 out of 17 children; (the discrepancy in the figures being explained by section with complete hysterectomy for 2 cases of cancer and one of ruptured uterus).

On the gynaecological side 806 operations were carried out in all, chiefly opening of abscesses, ventro-fixation of the uterus, dilatation of the cervix uteri, repair of vesico-vaginal fistula, salpingectomy, etc. The number of deaths was 27 or 3.3 per cent.

Although this report is presented in the form of statistical tables, yet it will interest all practising obstetricians in India.

REPORT ON THE PUNJAB MENTAL HOSPITAL, LAHORE, FOR THE YEAR 1924. BY COLONEL C. H. BAKHLE, I.M.S., I.G.C.H., PUNJAB. LAHORE: SUPDT., GOVT. PRINTING, PUNJAB, 1925. PRICE, RE. 1-4-0.

THE daily average population of the Mental Hospital in 1924 was 24.26 less than in the previous year, the decrease of about 3 per cent. being attributed to the fact that the charge for maintenance of patients was raised at the beginning of the year from Rs. 16 to Rs. 20. This conclusion is borne out by the figures as to receipts from paying patients which, even allowing for arrears not yet collected, did not increase to anything approximating the rate of increase in the fees. Even with this decrease the daily average population was in excess of the capacity of the hospital, and at times the overcrowding was excessive. The Inspector-General of Civil Hospitals observes that the completion of the new criminal section with accommodation for 200 patients will relieve the congestion in the male hospital, but that this section has not yet been occupied as Government sanction has not yet been received for the extra staff that will be necessary. Other improvements in the accommodation for patients and staff have been held up owing to the necessity for economy in recent years, but it is hoped that most of the deficiencies will be remedied in the current year.

The increase in the number of cases discharged as cured,—a number amounting to about 16 per cent. of the daily average population,—is a most satisfactory feature of the year's report, and in view of the results obtained the slight financial loss due to the freer employment of patients in open air occupations may be disregarded.

The death rate was higher than in the previous year, amounting to 11.31 per cent. of the daily average population. This, however, is equal to a rate of only 12.8 per mille as compared with the general provincial rate of 43.4 per mille, and, considering the peculiar nature of the population concerned, the figures bear eloquent testimony to the care with which the inmates of the institution are looked after.

The expenditure per head of the daily average population, excluding expenditure on work done by the Public Works Department, amounted to Rs. 294 as compared with Rs. 287 in the previous year.

Captain C. J. Lodge Patch, I.M.S., was in charge as Medical Superintendent throughout the year, assisted by Dr. Thomas, the Deputy Medical Superintendent. The Revd. Mother Superior and the Franciscan Sisters continued to discharge their voluntary duties of looking after the female-patients in the hospital with the same self-sacrifice as in previous years.

ANNUAL REPORT ON THE PATNA MENTAL HOSPITAL FOR THE YEAR 1924. By LIEUT.-COL. H. R. DUTTON, M.R.C.P., I.M.S., SUPERINTENDENT. PATNA: SUPDT., GOVT. PRINTING, BIHAR AND ORISSA, 1925. PRICE, RE. 1.

THIS report by Colonel Dutton contains interesting matter, and should be read in the original by medical officers concerned with prisons and mental hospitals in this country.

The number of patients at the beginning of the year was 284; 70 were admitted during the year; and the average daily strength was 243. Recoveries numbered 35. "The question of discharge of those patients (mostly females) who have recovered, but are more or less friendless and homeless, is a difficult problem to solve," writes Colonel Dutton.

"It is considered unwise to throw them out on the world, because if discharged the stigma of being in a mental hospital is likely to stand in their way of getting any employment or a shelter and in consequence they will gradually swell the number of beggars, or most likely of criminals or 're-admitted' cases. On the other hand all authorities agree that they should never be kept within the precincts of a mental hospital, where the surroundings are certainly not congenial and common humanity demands that they should be segregated from insane persons as soon as they are convalescent. Under existing conditions they soon contract an 'asylum habit' and thus become a continuous burden to the State.

I would therefore suggest for the consideration of the Government the desirability of construction of separate convalescent wards, outside the boundary wall of the hospital, and the opening of classes in various branches of home industry under properly trained work-master and work-mistress, and would also draw the attention of the generous public to the urgent necessity of starting 'homes' and agricultural farms for these unfortunates."

The number of patients treated for disease other than mental was 376, with a daily average sick rate of 34.9; dysentery and ankylostomiasis were the two chief complaints; and it is especially difficult to keep down the incidence of these diseases in patients in a mental hospital many of whom are of filthy habits, and often both coprophagic and geophagic. Want of a proper segregation ward has been very much felt of recent years. Only five deaths occurred during the year, the lowest figures recorded since 1912.

The number of criminal lunatics has shewn a steady increase of recent years, and 131 were admitted during 1923. Colonel Dutton comments on this class of patient as follows:—

"Except in those cases where the accused persons are too insane to draw the attention of the trying Courts as to their mental condition, a plea of insanity is taken by the defence after some time has elapsed since the commitment of the crime, and the Court then directs the investigation of the mental condition of the accused. It becomes an extremely difficult problem for the medical men concerned to form any opinion at this stage as to whether or not the accused was of unsound mind at the time he committed the crime, and even if he was so, whether his unsoundness of mind was of such a nature as to have negatived his criminal responsibility. There is a possibility of miscarriage of justice one way or the other in such cases. Or cases may occur where

no such plea of insanity having been taken, and the mental disorder being of too trivial nature at the time of trial to escape attention of the Court, people have been convicted but while in prison undergoing the sentence, they show unmistakable signs of such types of mental disorder which cannot but be of a long standing nature. From the statement given above it will be noticed that amongst people convicted of crime but later showing symptoms of insanity, 2 (grievous hurt) suffer from dementia præcox, 1 (murder) suffers from epilepsy and 1 (murder) suffers from dementia paranoides. Now all will agree that the diseases mentioned above are of very very long-standing nature, starting possibly from childhood. It becomes then a pertinent question to ask as to whether or not these crimes were the direct result of their diseases, and if so the patients should not have been convicted at all. Then again the question of 'malingering' mostly among the convicts is a problem to be always kept in mind, the detection of which requires special observation and knowledge of mental disorders on the part of the prison authorities. Not infrequently cases of malingering have been mistaken for true insanity, due to either want of special knowledge or intelligent observation or collusion of the convicts with the warders staff.

To obviate the above-mentioned defects I would suggest that all prison doctors should undergo a thorough post-graduate training in a mental hospital, and that they should examine and record the mental condition of all prisoners, especially the under-trial prisoners, no matter whether a plea of insanity is taken or not. And in case of the latter, if they have reason to suspect any unsoundness of mind, they should voluntarily inform the trying courts of their finding and opinion."

The principal types of insanity dealt with were imbecility, dementia præcox, maniac depressive and confusional insanity, and epilepsy. One patient developed insanity shortly after an acute attack of malaria, and malignant tertian parasites were found in his blood. Puberty, adolescence, child-bearing, mental stress and strain, malnutrition and senility are all contributory ætiological factors.

An attempt was made during the year to issue plain clothing to all patients instead of the prison garb formerly in use. There was a sufficiency of blankets but other bedding could not be issued owing to stringency of funds. The scale of diet was improved, but—as Colonel Dutton remarks—one cannot expect much variety in diets when one cook on Rs. 12 p.m. has to cook for more than 300 patients a day! As no recreation hall is available, patients were taken instead in batches to a theatrical performance; whilst gramophones and playing cards were issued.

The total expenditure during the year was Rs. 77,563; or an average total per head of Rs. 260. With regard to the staff a serious position arose, but was boldly tackled.

"The work done by the subordinate keeper staff was, with a few exceptions, not altogether satisfactory. Owing to their ignorance, laziness and generally unsympathetic attitude, they failed to realize that this place was a hospital and the unfortunate inmates were patients to be nursed and looked after and not convicts under jail warders. When the present Deputy Superintendent, Dr. J. Roy, tried to inculcate the principles to be followed in the treatment of patients and insisted on the observance of rules laid down in the *Bihar and Orissa Lunatic Asylum Manual*, there was a general strike amongst the keeper staff. Dr. Roy managed the situation tactfully and brought round most of the keepers, but 13 remained obdurate. Both from considerations of discipline and of common humanity it was not possible to retain in the service men who refused to carry out orders given with a view to secure proper attention to the primary needs of the sick inmates of the mental hospital, and so I dismissed these 13 men from government service. This step undoubtedly produced some salutary effect, but still much remains to be attained. If the institution is to be looked upon as a hospital then the proper nursing and supervision of the patients should

be secured by the employment of an adequate number of nurses—male and female—recruited from fairly educated classes who can make intelligent observation about the conduct of the patients and also constantly supervise the work of these ignorant and illiterate keepers. I would therefore suggest that this point may be carefully considered while making appointments for the new hospital at Kanke."

In general, concludes Colonel Dutton, it is always extremely difficult to get correct and detailed information about the family and previous history of patients. The descriptive roll which accompanies the patient on admission has to be filled in by a police officer, and the information thus collected is quite valueless from either a scientific or therapeutic point of view.

Major A. W. Duncan, I.M.S. held charge of the hospital as Superintendent from July to November, during Colonel Dutton's absence on leave; whilst Dr. Jyotirmay Roy, M.B., D.P.M. (Eng.), returned from England, where he had received a special training in mental work, and was Deputy Superintendent throughout the year from January 25th.

The former mental hospital at Patna is to be done away with, and the new mental hospital for Indians at Kanke, Ranchi, is to take its place in 1926. It is hoped that the facilities afforded at Kanke will be very much better than those at Patna previously.

Correspondence.

UREA-STIBAMINE.*

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Of the pentavalent antimony compounds that are in common use in the treatment of kala-azar the preparation known as urea-stibamine is probably the one that has been used most extensively. At the Calcutta School of Tropical Medicine we have tried out a large number of antimony compounds and have selected a number of these as being of special value. When urea-stibamine was first introduced by Dr. U. N. Brahmachari and Mr. Judhistir Das, M.Sc., the former very kindly sent me a small sample of this preparation for trial; I only treated a few cases but the results were not very good. The published reports of other workers indicated that the preparation usually gave very much better results than I had obtained, but as I was unable to get further samples of this preparation I could not make a further trial of its therapeutic value for some time. During the last year however Dr. Brahmachari has very kindly given me a generous sample of his preparation and I have been enabled to treat a further series of cases; another small sample sufficient to treat one case was supplied to me by Mr. Chatterjee of the Chemical Department of this School, and the Union Drug Co. sent me a sample which they stated had been prepared according to Dr. Brahmachari's published formula.

The fact that urea-stibamine has not been widely used in our hospital has created an impression in certain quarters that we do not consider it a valuable drug in the treatment of kala-azar. This is of course not the case; and my letter is written with the intention of dispelling from the minds of your readers any impression of this nature.

I shall in due course publish the final results of the treatment of this series of 36 cases; but as there is no means by which one can be absolutely sure that a patient is cured, even spleen or liver puncture occasionally giving misleading results, it is my usual

* Please see footnote on p. 162 in which it is shewn that the name urea-stibamine may not be used by any manufacturer of this substance, except Dr. U. N. Brahmachari. We understand that the Union Drug Company are now placing the same compound on the market under the name "Stiburea."—EDITOR, I.M.G.

practice to follow cases up for at least six months before assuming that they are finally cured.

The immediate results of treatment can be summarised as follows:—

Thirty cases were discharged cured, two cases had a course of treatment which should have been sufficient to cure even a resistant case, but they did not improve at all under treatment; two only had a short course of injections but insisted upon a premature discharge from hospital; these were clinically improved but still harboured the parasites of the diseases; and two died during the course of treatment.

Of the 30 cases that were discharged cured 25 had previously received no form of treatment; the mean of the number of injections which were administered to these was 12.1 and the mean of the total relative dose was 3.16 grammes per 100 lbs. body weight. The 5 cases that had previously received a full course of treatment and had subsequently relapsed received a mean number of injections of 15.8 and a mean total relative dose of 4.6 grammes per 100 lbs. body weight.

The reduction of the temperature was in most cases rapid, one case was afebrile throughout the course of injections and three other cases ran an irregular temperature throughout which fell to normal immediately the treatment was discontinued. Of the remaining 26 cases the mean of the number of injections that were administered before the definite cessation of fever was 5.5.

In every case the diagnosis was made by spleen or liver puncture and the cure confirmed, as far as it is possible to confirm it by this means, by spleen or liver puncture with culture of the material.

Comparison of the two brands of urea-stibamine:— There does not appear to be any difference between the therapeutic action of each of the two principle brands of the preparation which we used. Twenty-two cases were treated with the sample sent to me by Dr. Brahmachari and thirteen with the sample received from the Union Drug Co. Of the deaths that occurred one was in each series. The two cases that resisted treatment were in the former series but both of these cases have resisted all forms of treatment and are still uncured. The mean total relative dose that was administered to the previously untreated cases was 3.14 grammes in the former series and 3.17 grammes in the latter and the total number of injections was 12.7 in the former and 11.3 in the latter. The rate of fall of temperature was also almost equal in the two series; in the former series the mean of the number of injections administered before the cessation of fever was 5.6 and in the latter series 5.3.

The toxicity of the various samples submitted for trial was tested very carefully before use; the relative toxicity to mice appeared to be practically the same in each sample tested and I am told by Major R. N. Chopra, who is at present engaged in investigating the various antimony compounds pharmacologically, that the action on blood pressure and respiration is almost exactly similar in the case of the Union Drug sample and a sample that he purchased from Messrs. Bathgate & Co., labelled "Urea-stibamine (Brahmachari)".—Yours, etc.,

L. E. NAPIER, M.R.C.S., L.R.C.P.
Kala-Azar Research Worker.

SCHOOL OF TROPICAL MEDICINE,
CALCUTTA,
18th February 1926.

MEDICAL RELIEF IN INDIAN RURAL AREAS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Medical education in India is becoming more and more difficult every day, more costly, and of longer duration, especially in the Calcutta University where the course lasts six years, and where some students even take eight, nine or ten years to qualify. On the other hand the need in the *mofussil* for doctors of the assistant surgeon class is very acute; it is easy enough to get men of the assistant surgeon class in Calcutta,

yet in the *mofussil* areas it is very hard to find one within a five mile radius. In comparison with the conditions in other countries the provision of skilled medical relief in the rural areas of India is inadequate. People in Calcutta have ready access to qualified medical men, lady doctors, qualified midwives; but the want of such provision in the *mofussil* is acute. It is often impossible for a *mofussil* patient to find a qualified medical man within five miles of his home, and the greater the distance the doctor is called, the greater his fee. The sub-assistant surgeons who do see such patients, are often hard put to it when a second opinion is wanted, as no doctor of assistant surgeon status is near.

Much is done by the medical mission hospitals. I cannot forbear in this connection to mention the work done by Dr. Muir when he was in charge of the Khulna Mission Hospital in the Burdwan district; within a radius of ten or twelve miles of his hospital medical relief was afforded extensively to the masses, men, women and children alike.

A very considerable proportion of students at the Calcutta Medical College qualify in their sixth year, and thanks are due to the Senate of the University for the very large numbers of qualified medical men which they pass into practice. But cannot something be done to increase the number of trained medical men of assistant surgeon grade in the *mofussil* areas?—Yours, etc.,

S. P. NAG, L.M.S.

GOZINA, DASPUR,
HOOGHLI DISTRICT,
3rd February 1926.

QUACKERY IN THE MOFUSSIL.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the interests of the public safety it is high time that something was done to put a stop to the pernicious habits of medical quacks in India. Many lives are lost owing to the use by these gentry of excessive and disproportionate doses of poisonous drugs. Being blissfully ignorant of the correct posology, they will not hesitate to administer any dose whatever, when the qualified medical man will think not twice but thrice before he prescribes at all. Were the village quack innocuous, he might be tolerated; when he becomes a danger to the lives of the community, it is time that he should be suppressed. And dozens of patients die, with their relatives in complete ignorance of the fact that it is the quack "doctor" who has killed them.

The present is the age of injections. Even illiterate village folk prefer to have what they term "injunctions" by way of treatment of difficult cases. The quacks—whose numbers are legion—are one and all armed with a cheap Japanese hypodermic syringe, and they will administer anything or everything hypodermically; if strychnine succeeds with one patient it is tried on the next, with little or no regard paid to dosage.

Further, these "doctors" have each their own coterie of supporters—whether interested or disinterested financially—more usually interested, since those who are disinterested are but few among many. To the ordinary humble villager it would appear as if the quack, with his modern syringe and his armamentarium of hypodermic drugs at the cheapest of rates per visit, is a boon from Heaven; the other side of the shield has never been shewn to these people.

Something should be done to put a stop to the universal illegitimate medical quackery in India. I know but little of homœopathy, but I understand that its cardinal principle is the administration of excessively minute doses of drugs which will produce symptoms analogous to those from which the patient is suffering. Perhaps the quacks could be compelled by law to become homœopaths, and to administer only homœopathic doses: their mistakes as to dosage, etc. would then be far less dangerous.

There are various ways of killing people and there are also various ways of declaring such methods illegal.

But not only is the quack who kills his patients exempt from prosecution and responsibility; he is actually paid a fair remuneration by the relatives of the deceased for having killed him.

We—duly qualified medical men—receive scores of official circulars about the necessity for keeping all poisonous drugs in a "poisons' almirah"; the key of which is not even to be trusted to our own compounders. But the village quack is allowed free and unlicensed use—hypodermically, as often as not—of the same poisonous drugs; he may administer them in any dose, and in complete ignorance of their actions.

In the name of common humanity I would appeal to Government to do something to stop this dangerous and criminal system of universal quackery, whereby the lives of our people are endangered and often lost.—Yours, etc.,

H. DAS GUPTA,
Bengal Medical Service.

DAULATPUR, KHULNA,
6th February 1926.

"THE TREATMENT OF MALARIA WITH PERACRINA 303."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In common justice to myself and to the manufacturers of Peracrina 303, I feel it my duty to comment shortly on the article by Dr. William Fletcher, published under the above title in the *Indian Medical Gazette* for November 1925.

To begin with, Dr. Fletcher's disparagingly worded conclusion as to the composition of Peracrina 303, though apparently contradictory to the description given of the drug by the makers, does not in reality essentially differ from it. It is well known to every analytical chemist and every qualified medical man that "yeast cells" consist almost entirely of albuminates rich in medicinal value, and that unless the cells were "dead," they could not be used in an inorganic chemical compound; further, that "a little starch" (or wheat flour) is invariably employed in the making up of pills, because of its binding properties. Acriflavine may be truthfully described as a "yellow dye," though "an acridine dye stuff" is, of course, a more exact definition.

The term "specific albuminates" is used by the makers with reference to chemical classification, rather than in the strictly medical sense. Had they been addressing the general public, they would have employed the practically synonymous and equally accurate expression "specially prepared yeast." Their advertisement, however, was intended for scientific men. I may add that the chemical process by which Peracrina 303 is manufactured is based on the English patent No. 208599/23.

The doses recommended in the advertisement are 6 to 12 pills daily for adults and 4 to 10 for children, according to the patient's state of health. This point is frequently emphasised in the Peracrina literature, where it is made perfectly clear that the medical man is quite at liberty to exercise his discretion and vary the dose.

That "it is impracticable to administer Peracrina for a long period.... in the large doses recommended by the makers," and that it "is too expensive for general use" are, no doubt, correct conclusions with regard to the Federated Malay States. Social and commercial considerations such as these are, however, surely out of place in a scientific treatise, apart from the fact that Dr. Fletcher is scarcely in a position to decide whether they are applicable to other countries.

The clinical tests made in Kuala Lumpur were of much too short duration for Peracrina to destroy the malaria parasites.

Dr. Fletcher's fifth conclusion is calculated to give a very misleading impression to the uninitiated. In the treatise on my experiences in the malaria districts of South Russia, I certainly stated that Peracrina "was found to be at least equal to quinine in the treatment of malaria," but I also laid stress on the fact that its action was essentially different. I do not advocate its

use "in place of quinine,"—to reduce high fever and effect an immediate but temporary cure; on the contrary, I have always declared that its anti-febrile properties are far inferior to those of quinine. I do, however, maintain that:—

(1) a complete course of Peracrina treatment (from six weeks to three months, or, occasionally, even a little longer) invariably cures chronic malaria completely and permanently by annihilating the parasites;

(2) in certain selected cases it may be used with advantage in combination with quinine to combat and finally completely cure acute malaria.

(3) It frequently proves effective in cases of so-called "quinine-resistance."

Even in the advertisement it is stated that during the first three weeks of treatment the blood tests may show an increase of parasites, and the temperature may rise. I account for this on the theory, justifiable by the well-known properties of its components, that Peracrina forces the parasites latent in the spleen and other affected organs to come out into the peripheral blood, where it is able immediately to combat and ultimately to annihilate them. This theory is confirmed by the speedy return of the spleen to a normal size, a characteristic symptom totally ignored by Dr. Fletcher.

(I should mention, too, that not only "the clinical histories of three cases" cited by Dr. Fletcher, but also several others, were reproduced as illustrations in my treatise.)

In view of the statements made by Dr. Fletcher under the heading "Clinical Tests of Peracrina in Kuala Lumpur" (paragraphs 1 and 2), it is comprehensible that he found the drug little suited for use in the hospitals of the Malay States. As, however, the conditions there are such that "it was impossible to give them (the patients) the three months' treatment recommended by the Haco Company," (he "was not able to detain these people in hospital for more than ten days or a fortnight"); and that "the question of permanent cure cannot be investigated accurately," he would, in my opinion, have shown a more open-minded spirit, (if, indeed, he experimented at all in the circumstances), had he refrained from writing and publishing an article in a tone calculated to deter others, perhaps more favourably situated than himself, from testing the value of Peracrina 303.—Yours, etc.,

J. WALKER, M.D.,
Médecin adjoint du Laboratoire
Bactériologique à Elisabethville,
Prov. Katanga, Congo Belge.

BRUSSELS,
2nd February 1926.

(Note.—The above letter is published with a view to enabling our readers to hear the case for Peracrina as well as the case against. We are still unconvinced that any evidence has been produced of the curative action of Peracrina, but, doubtless the firm which issues the drug will take care that all possible evidence in its favour will be made available. EDITOR—J.M.G.)

THE PROVOCATIVE DIAGNOSIS OF MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the two methods of driving parasites from the spleen into the peripheral circulation as described by Lieut.-Col. Jeudwine in last month's issue of the *Gazette*, there is another method which I have just been acquainted with, viz., the administration of amidopyrin. By E. Merck's Annual Report for 1917-1921, just to hand, on page 23, under amidopyrin it is stated, "according to H. Mautner, this preparation can be used in latent malaria to provoke an attack. If a dose of 0.7 gm. per diem be given for eight consecutive days an attack will as a rule occur on the fourth or seventh day. There is at present no explanation offered for this action."—Yours, etc.,

BETEL-CHEWERS' CANCER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—As a rejoinder to the article which appeared in your issue for January, 1925, on the causation of betel-chewer's cancer, the following facts may perhaps be cited.

Buccal cancer is quite common among people who do not chew betel, so it is not safe to assume that the lime in the chewing mixture is the sole agent responsible. Even in methods of preparing and taking the chewing mixture there are variations in different parts of the country. In Malabar a quarter of a betel leaf, with a few grains of lime (*chunam*) smeared on it, and two or three fragments of areca nut forms the initial part of the "chew." After this mixture has been well chewed a piece of tobacco—some 2 to 6 drachms in amount—is then put into the mouth and kept with the original bolus in one corner of the mouth. Some will keep the "chew" in the mouth for only a few minutes, others for hours.

In the Tamil districts in South India, the "chew" differs considerably. Some take a dozen or two betel leaves with some two drachms of *chunam*, and insert the leaves one after another, smeared with *chunam*, into the mouth, which already contains about half an ounce of areca nut shavings; they do not usually use tobacco. Others use tobacco, but in very small quantities. In Malabar the addition of tobacco is universal amongst male members of all castes, and among all females—with the exception of Brahmins. In Tanjore and other Tamil districts both sexes of all castes, except Brahmins, add tobacco. Only a few Brahmin males however use tobacco.

On the Malabar side cancer is more common than in Tanjore and its adjacent Tamil districts. Buccal cancer is very rare among Brahmin ladies, though they chew more often and in more quantity than others. In Tanjore cancer is rarer among Brahmins of both sexes than amongst non-Brahmins.

Tobacco is a plant in universal and world-wide use. May it not have something to do with the incidence of buccal cancer? In clay-pipe smoker's cancer, may it not be the tobacco and not the pipe which is the cause? The irritant properties of *chunam* may have little or nothing to do with buccal cancer. Further, there is a custom in some parts of Southern India for people to insert a long piece of tobacco into the rectum to relieve constipation. A male patient recently consulted me who had cancer of the rectum; he gave a history of having frequently inserted a piece of tobacco some two inches in length into the rectum for the previous 15 years, in order to secure a daily evacuation of the bowels.

In brief, it seems to me that tobacco may be the element to be incriminated in the betel-chewer's mixture.—Yours, etc.,

ALIPURAM JAIL, BELLARY.
8th January 1926.

A FORMULA FOR INTRAVENOUS IODINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I read with much interest the notes on the treatment of pneumonia and of cellulitis in your issue for last December by my friend, Dr. S. N. Datta, L.M.P. I would like to mention, however that the following solution, which was advocated by Colonel Jeudwine in your issue for December 1923, appears to be less irritant and more useful than the use of the tincture:—

R Potassium iodide	36 grains.
Iodine, pure	24 grains.
Distilled water to	1 oz.

Dose; 1 to 2 c.c. diluted with 8 c.c. of distilled water. Each c.c. of the above solution contains one grain of iodine.

As a rule injections need not be given on alternate days; once a week is usually sufficient. I have tried

these injections with admirable results in cases of pneumonia, pleurisy, cellulitis, septic wounds, chronic bronchitis, carbuncle and rheumatism, and my notes on "The Treatment of Carbuncle by Intravenous Iodine" appeared in the *Indian Medical Journal* for September, 1925.

I tried the same treatment in two cases of phthisis, but the results were disappointing; both patients died.

I am indebted to my chief, Dr. E. A. Goldie, M.B., B.S. (Lond.), for useful suggestions in connection with this method of treatment.—Yours, etc.,

M. BAROOA, L.M.P.

DIBRUGARH, ASSAM,
8th January 1926.

Service Notes.**THE NEW DIRECTOR-GENERAL, INDIAN MEDICAL SERVICE.**

We have to congratulate Major-General T. H. Symons, C.S.I., O.B.E., K.H.S., I.M.S., formerly Surgeon-General with the Government of Madras, upon his appointment as Director-General, Indian Medical Service, with effect from the 1st April, 1926.—EDITOR, I.M.G.

APPOINTMENTS AND TRANSFERS.

The services of Lieutenant-Colonel T. H. Gloster, M.B., I.M.S., an officer of the Medical Research Department are placed at the disposal of the Government of Madras, with effect from the afternoon of the 28th January 1926, for appointment as officiating Director, Pasteur Institute, Coonoor.

Lieutenant-Colonel A. B. Fry, C.I.E., D.S.O., M.D., I.M.S., Professor of Hygiene, School of Tropical Medicine and Hygiene, Calcutta, is appointed to act as Principal, Medical College, Calcutta, in addition to his own duties, with effect from the 20th October 1925, *vice* Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., M.D., F.R.C.S.E., I.M.S., granted leave.

Lieutenant-Colonel N. M. Wilson, O.B.E., I.M.S., is appointed temporarily to officiate as Civil Surgeon, Simla West, with effect from the date on which he takes over charge from Lieutenant-Colonel Hallilay and until Lieutenant-Colonel Jeudwine's return from leave.

In modification of previous orders, Lieutenant-Colonel H. Hallilay, M.B., I.M.S., is appointed temporarily to officiate as Civil Surgeon, Simla (West), up to the 28th February 1926, or the date on which he is relieved by Lieutenant-Colonel Wilson.

Major H. Hingston, M.D., I.M.S., First Resident Surgeon, Presidency General Hospital, Calcutta, is appointed to act as Professor of Clinical Medicine, Medical College, Calcutta, and Second Physician, College Hospital, with effect from the 1st November 1925, *vice* Major J. D. Sandes, M.D., F.R.C.P.I., I.M.S.

Major J. D. Sandes, M.D., F.R.C.P.I., I.M.S., officiating Professor of Clinical Medicine, Medical College, Calcutta, and Second Physician, College Hospital, is appointed to act as Professor of Medicine of the said institution, and First Physician, Medical College Hospital, with effect from the 1st November 1925, *vice* Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., M.D., F.R.C.S.E., I.M.S., granted leave.

Major E. W. O'G. Kirwan, M.B., F.R.C.S.I., I.M.S., is appointed to act as Professor of Ophthalmic Surgery, Medical College, Calcutta, and Ophthalmic Surgeon, College Hospital, *vice* Lieutenant-Colonel W. V. Coppinger, D.S.O., I.M.S., going on leave.

Major S. S. Sokhey, I.M.S., is appointed temporarily to the Medical Research Department and posted as supernumerary officer at the Haffkine Institute, Bombay, with effect from the 18th August 1925. His services are placed at the disposal of the Government of Bombay for employment as officiating Assistant Director of the Institute, with effect from the date on which he assumes charge of the duties of the appointment.

APRIL, 1926.]

Major A. N. Dickson, I.M.S., an Agency Surgeon, is posted as Agency Surgeon in Bundelkhand, with effect from the 30th January 1926.

Major P. F. Gow, D.S.O., M.B., I.M.S., officiating Civil Surgeon, is transferred from Jalpaiguri to Murshidabad, vice Dr. Debendra Nath Hazra, transferred.

The services of Captain Haji M. Salamat-ullah, M.C., I.M.S., are placed temporarily at the disposal of the Government of the United Provinces, for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

The services of Captain B. G. Mallya, I.M.S., are placed permanently at the disposal of the Government of Bengal, with effect from the 19th October 1925, for employment in the Jail Department.

Captain R. Hay, I.M.S., an officiating Agency Surgeon, is posted as Medical Officer, Sistan Consulate, with effect from the 12th February 1926.

Subject to His Majesty's approval, the under-mentioned officer has been appointed permanently to the Indian Medical Service, as Lieutenant, by the Right Hon'ble the Secretary of State for India. His commission will bear the date 16th December 1925:—

Victor Alexander Edge.

LEAVE.

Major K. S. Thakur, I.M.S., Civil Surgeon, Bakarganj, is allowed combined leave out of India for ten months and seventeen days, with effect from the 25th January 1926, or from any subsequent date on which he may avail himself of the leave.

RELINQUISHMENT OF RANKS.

Major (now Lieutenant-Colonel) R. M. Carter, C.B., F.R.C.S., I.M.S., relinquishes the temporary rank of Lieutenant-Colonel on ceasing to be specially employed on 17th April 1919.

RETIREMENTS, ETC.

The King has approved the retirement of Lieutenant-Colonel R. M. Dalziel, M.B., F.R.C.S.E., I.M.S., with effect from the 29th January 1926.

The King has approved the transfer to the temporary non-effective list of Captain P. M. Antia, I.M.S., with effect from the 21st November 1925.

PROMOTIONS.

Major M. A. Coullie, I.M.S., whose retirement was notified in the *London Gazette*, dated the 16th October 1925, is granted the rank of Lieutenant-Colonel.

Captain N. M. Mehta, I.M.S., to be acting Major whilst holding an appointment with the Egyptian Expeditionary Force, from 22nd November 1918 to 24th December 1919.

NOTES.

TRYPARSAMIDE, MAY AND BAKER.

An interesting evidence of the increasing enterprise of British chemists is that Messrs. May and Baker of London have taken up the manufacture of tryparsamide, under licence from the Rockefeller Institute for Medical Research in New York. This interesting new arsenical compound is the sodium salt of N-phenyl-glycine-amide-p-arsonic acid, and is a white, colourless, crystalline, freely soluble powder. Introduced primarily for the treatment of sleeping-sickness in man, by the American workers, the drug has also a limited rôle of value in the treatment of meningo-vascular syphilis, general paresis, and tabes dorsalis, especially in the treatment of early cases of such conditions. In surra, reports are so far rather disappointing, but further investigation is called for; and it is in India especially that such investigation could be best carried out. Messrs. May and Baker publish a small brochure on tryparsamide, which may be of interest to both medical and veterinary workers in this country.

LEITZ'S MANUAL ON THE USE OF THE MICROTOME.

AN exceedingly valuable, instructive and well illustrated manual on the use of the microtome has been published by the well-known firm of Ernst Leitz of Wetzlar, a copy of which is given free to every purchaser of a Leitz microtome. The manual is the work of Dr. S. Becher, Professor of Zoology and Comparative Anatomy in the University of Giessen, and is now in its third edition. In 45 pp. the author fully explains the use of different types of microtome, the processes of section embedding, paraffin embedding, combined embedding, and the various cutting methods with different models, and the use of the freezing microtome. The brochure will be of great interest to all laboratory workers, and is a most handy and convenient one to consult. The English agents are Messrs. Ogilvy and Co., 20, Mortimer Street, London, W. 1.

REAGENTS CATALOGUE. THE GENERAL CHEMICAL CO., NEW YORK.

We have received from the General Chemical Co., 40, Rector Street, New York, a copy of their new catalogue No. 85 of chemical reagents. For two generations the firm of Baker and Adamson have been famous in America for their association with research and analytical work, and the "B and A." products of the General Chemical Co. are well-known. The present catalogue presents a list of some 950 products, alphabetically arranged. The analyses given shew that the utmost standard of purity of these reagents is insisted upon, and the catalogue is one which will greatly interest chemists, laboratory workers and research students. The prices given are F.O.B., but on p. 4 a list of package charges is also added; whilst every article has a code number assigned for use in cabling, and those which cannot be exported are marked with an asterisk.

THE "LABAT" OUTFIT FOR LOCAL AND SPINAL ANÆSTHESIA.

We have received from the Anglo-French Drug Co., Ltd. one of their "Labat" outfits for local and spinal anæsthesia.

A glass syringe is used in preference to an all-metal one, since it is absolutely necessary to control its contents at any stage of the procedure, especially when aspirating blood or cerebro-spinal fluid, when the needle has been introduced in the vicinity of large blood-vessels or close to the vertebral column, or within the sacral canal. Leakage of the plunger with a back flow of the anæsthetic fluid is noticed immediately, and the knowledge of the quantity of fluid injected is accurate, which is of some importance when the 1 or 2 per cent. solution is used.

The barrel of the syringe is, therefore, of transparent glass, which is more easily cleaned, but its plunger is metal. Both parts are ground to fit each other airtight. The barrel has a capacity of 12 c.c.; but the graduation at its distal end leaves a space of 2 c.c. behind the plunger, thus making aspiration possible as soon as the syringe is connected with the needle and before any fluid is injected. The barrel is closed by a

FIG. 1.

metallic cover screwed on to it and provided with suitable wings for a good and easy grasp during the manipulations (Fig. 1). Its distal end bears an eccentric

tip for adjusting the needle, and a bayonet lock which prevents the needle from flying off the syringe under pressure (Fig. 2). The eccentric position of the

FIG. 2.

needle facilitates injection parallel with the surface of the skin and makes it easy to manipulate on very lean patients, especially in regions in which the prominences of the framework stand in the way. Screws for fixing the needle to the syringe are of no practical value, since the needle has very often to be introduced repeatedly apart from the syringe, Farr's pneumatic injector and self-filling syringes are contrivances which might be of some value for local infiltration; but these instruments do not suit the purpose of nerve blocking, since definite small quantities of fluid must be injected slowly in the close vicinity of each nerve to be blocked.

FIG. 3.

FIG. 4.

Needles.—The thinner the needle, the less the trauma to the tissues, blood-vessels or nerves; but the gauge of the needle should be suitable to its length and such as would delicately transmit to the fingers an expression of the nature of the tissues approached in the deep structures of the body. Regional anaesthesia needles should be flexible, but should not bend; they should be able to pass through all soft tissues with almost equal ease. They are, therefore, made of steel, highly polished or nickel plated, and have a long bevel with a very sharp point, so as to render their manipulation painless.

One set of needles is sufficient to meet the requirements of the various procedures for inducing regional anaesthesia. It is composed of:—

FIG. 3.

- The finest intradermal needles (No. 1)
- Two 50 mm. needles (No. 2).
- Two 80 mm. needles (No. 3).
- One 100 mm. needle (No. 4).
- One 120 mm. needle (No. 5).

FIG. 4.

Two spinal puncture needles.

Each needle is provided with a metallic shield to protect its point and a brass wire or stylet to prevent its obliteration.

The spinal puncture needle is made of nickel, and, being unbreakable, is preferred to the steel needle for

epidural or caudal block. The special bevel is of great value in puncturing the sacro-coccygeal membrane and advancing the needle up into the sacral canal. The length of the needle is 80 mm. and its thickness is 1.1 mm.

The outfit is very well made; it will be found suitable for taking blood for culture and for intravenous medication as well as for local anaesthesia and lumbar puncture.

MESSRS. E. MERCK'S ANNUAL REPORT FOR 1925.

We have received from Messrs. E. Merck, Chemical Works, Darmstadt, a copy of their annual report for 1925. It need hardly be said that this firm is one of world-wide reputation for the supply of purified and reliable chemicals and drugs, and this booklet of 492 pp. affords very interesting reading. Its general plan is to review the different preparations and drugs manufactured by the firm, in alphabetical order in the first 459 pages; and here the reader will find, not only a succinct and very readable account of each preparation or drug in question, but also a very complete bibliography. The publication covers all advances in pharmaceutical chemistry and therapeutics in the years 1917-1921, and it will be found to be of great interest not only to pharmacologists but also to the general practitioner. Further, the work is very fully indexed; there being a general index, as well as a special index of diseases, symptoms and indications for treatment. A third—bibliographical—index, of eight pages, shews how enormously wide a range of medical journals has been consulted in putting the work together. In brief this "annual" report is something very different from an annual report, it is a valuable guide to present-day therapeutics, fully referenced and very complete, put together with true German thoroughness.

No price is stated with regard to the report, which we presume is for circulation especially to medical practitioners and pharmacologists; but its value, both for the general practitioner and the experimental pharmacologist, is very great.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

SOME FACTORS AFFECTING THE PROPAGATION OF HOOKWORM INFECTIONS IN THE ASANSOL MINING SETTLEMENT, WITH SPECIAL REFERENCE TO THE PART PLAYED BY COCKROACHES IN MINES.

By ASA C. CHANDLER, M.S., Ph.D.,

(Contribution from the Hookworm Research Laboratory, Calcutta School of Tropical Medicine and Hygiene.)

IN connection with a field inquiry into the prevalence and epidemiology of hookworm infections in India, financed in part by a grant from the Indian Research Fund Association, an investigation was made of the factors influencing the propagation of the infection in the Asansol Mining Settlement of Western Bengal. Although the results of this investigation will be published in full in the *Indian Journal of Medical Research* at a later date, it seems advisable to call attention to some special points which were brought out and which have been particularly investigated. Special attention was paid to the distribution and fate of stools deposited on the surface of the ground and in the underground coal mines of the Settlement.

Surface infestation of the ground in the Asansol area is definitely limited to about five or six months of the year, from the middle of June to the end of November; during the rest of the year the dryness of the ground almost entirely does away with the probability of infection being acquired. In the winter months the temperatures are low enough to retard the development of the larvæ so that, in spite of occasional showers, the ground, which is gently rolling and from which surface water quickly runs off, probably very rarely remains moist long enough to permit the larvæ to reach the infective stage, except in very localised and exceptional situations, e.g., at the edge of a tank. In the pre-monsoon period from the beginning of March to the middle of June the sun is extremely hot and the ground becomes parched and baked in a very short time. There are fairly frequent showers in May and early June, and sometimes earlier in the year, but only exceptionally is there sufficient moisture at the surface of the ground on the sites selected as defæcation areas to allow hookworm larvæ to live for the five days necessary to reach the infective stage. There is very little deep shade in the area and the stools are deposited either on the surface of dry parched fields exposed to the full glare of the sun, or else in lightly shaded groves at the edges of the villages or *dhowras*. The Scarabæid beetles,

which are very active in mixing faeces with soil during the wet season, and thereby greatly assist the development of hookworm larvæ, bury themselves at a considerable distance below the surface of the ground during the dry season, and remain inactive until the ground again becomes moist. There was found to be an almost complete cessation of work on the part of these insects in February and March, when investigations were being made in Western Bengal. For these reasons hookworm infection in Western Bengal, among the agricultural people, is comparatively very low in spite of defæcation habits which are ideal for the propagation of the infection. No latrines of any type, or even bricks or logs for standing on during defæcation, are in use among the people in this part of Bengal. The stools are scattered over fairly extensive defæcation areas with no tendency to the use of natural standing places, beneath which the faeces accumulate in masses; such places are common in some parts of Bengal, and are not as favourable for hookworm development as the scattered pollution found near Asansol. In a village, Ratibati, in the Asansol Mining Settlement, which was carefully studied in February, although the incidence of infection was found to be 88.6 per cent., the average eggs per gram of faeces was only 421 and the index of infection 164. This indicates an average infection of about 18 worms per person. Tomb (1923), in his study of hookworm infection in this area, found an incidence of 43.32 per cent. among the low-caste village inhabitants by Lane's levitation method of diagnosis, which is less accurate than the newer D. C. F. method which we used. Tomb found an average of about nine worms per person among these village inhabitants, basing his estimate on worms recovered after anthelmintic treatment with thymol (60 gr.). There are several reasons why Tomb's estimate is lower than mine. It is never possible to expel all the worms by anthelmintic treatment; in a place where *Ancylostoma duodenale* constitutes about 30 per cent. and *Necator americanus* 70 per cent. of the worms harboured, as Tomb has shown to be the case in the Asansol area, 60 grs. of thymol cannot be expected to remove more than about 80 per cent. of the worms; there is further loss due to the elimination of worms later than 48 hours after treatment (Tomb does not say for how long the stools were saved after treatment; it is seldom possible even under hospital conditions to get Indians to save all the stools for more than a day), and finally a certain percentage of worms are lost by maceration or otherwise escape notice. One other factor also comes into play; Dr. Tomb's work extended over a considerable period of time, and it is very likely that many, possibly all, of his village

observations were made during the time of year when infection is low, whereas mine were made within a month after the season of maximum infection, which would be about six weeks after the drying up of the ground (about the beginning of January). There can be little doubt but that infection takes place freely during the five or six months of the year that the ground is moist, but since it has been shown by Chandler (1926) that in the absence of re-infections hookworm infections are reduced about 50 per cent. in three months and about 60 per cent. in six months, it is evident that at the beginning of each successive wet season the number of eggs reaching the ground, and which bring about soil infestation, must be relatively low; during the course of the wet season, as new worms are acquired and the infection increases, heavier and heavier infestation of the ground develops, but after this has gone on for five or six months the soil infestation is again destroyed by desiccation and re-infection is thus stopped. Instead of a cumulative increase in infection up to a high point of equilibrium, where the number of worms lost keeps pace with the number of worms acquired, such as occurs in many parts of the West Indies, where the rain is distributed throughout the year, there is a cumulative increase for only a few months, which is then brought back to a low point by a 60 per cent. decrease before conditions are again favourable, etc. It is significant that in spite of the fact that almost everywhere in India hookworm infections are light, wherever Indian labour has been transplanted to other countries where there is no protective dry season, e.g., West Indies, Fiji, Malaya, etc., intense infections develop in the very people who in their own country suffer very little.

In the underground coal mines environmental conditions are very different from the surface conditions, and are extremely favourable for the development of hookworm larvæ throughout the year. The temperature is moderately high at all seasons, ranging between 80° and 90° F., which is optimum for larval development and growth. The air is at all times near the saturation point as regards moisture, so that desiccation does not come into play at all. The defæcation areas usually selected are galleries running off from the main avenues of communication, where mining operations have been discontinued. Frequently galleries are selected near a stream where water for ablution can be obtained. The mine water was examined and found to be slightly alkaline (about pH 7.7) without any demonstrable quantities of the heavy poisonous metals in solution, and therefore not injurious to the development of the larvæ. At the edges of the streams the rock or coal floors, covered with coal dust and fragments of coal, are often kept moist by

spray from the flowing stream, or from water scooped up for ablution. In such places conditions for the development of hookworm larvæ are obviously nearly ideal. Some of these places were found to be very frequently used and fresh stools were always in evidence. More scattered pollution was also found in other galleries away from water, and even occasionally along the sides of the main avenues of communication, where there was frequently flowing water.

Particular investigations were made in a mine which Dr. Tomb has found to be rather more heavily infected than the average. An examination of 75 individuals living in the coolie lines of this mine, about equally distributed among males, females and children, however, showed that the infection among these people was actually *lower* than in the village group studied. The incidence of infection was 88 per cent., the average eggs per gram of fæces only 223, and the index of infection 128. This would indicate an average of only about ten worms per person as compared with an average of 28 found by Dr. Tomb among underground workers. However, many of these individuals undoubtedly did not work underground in the mines and were not exposed to mine infection. Since there was even less shade here than in the village studied and since the defæcation area was on a ridge from which the water would run off very quickly, a lower degree of infection than in the village would have been expected. In the mine itself, however, twelve fresh stool samples were collected and examined. Six of these were scattered stools, while six were taken from a much frequented disused gallery beside a water course. Of the first six, five were infected, the average eggs per gram was only 167, and the index of infection 101. Of the other six all were infected, the average eggs per gram was 1080, and the index of infection 325, which falls into the category of moderate instead of light infections. In spite of the small number of stools on which this difference is based, it seems to me it has some significance and is not the result of mere chance.

Observations were made on the fate of stools deposited in the mines. It has already been remarked that conditions were such as to prevent desiccation; there were no Scarabæid beetles or ants to carry away the fæces or to mix them with the substratum; and there were no domestic animals to devour them. Nevertheless it was evident that the stools were disappearing at a very rapid rate. For although fresh scattered stools could be found at any time, any traces of old stools were very difficult to find. Only in the defæcation area above mentioned where there was daily a considerable accumulation of fresh stools by the side of a stream was

there any evidence of old stools, and even here there were only small remnants of old stools to be found, consisting mainly of the larvæ and pupæ of a small *Fannia*-like fly, with very little actual fecal material but a considerable accumulation of fly droppings. Where stools had formerly been, a white deposit was found on the coal resembling a deposit of lime; the true nature of this was not determined. In order to find out how readily hookworm larvæ actually developed under the existing conditions, twelve fresh stools were marked so that the substratum could be subsequently collected to investigate the amount of infestation resulting. Each was covered with a flat piece of coal and marked with a numbered piece of paper on a stick of wood. When these sites were examined five days later I was surprised to find no evidence whatever of the stools; they had completely disappeared leaving no trace except a slight white deposit on the coal, as previously described. From the scrapings of the substratum only small numbers of larvæ, from none to at most 33, were obtained. The reason for the disappearance of the stools, however, now became apparent, for under each piece of coal were found numbers of large cockroaches (*Periplaneta americana*). These cockroaches were, in fact, found to be extremely numerous throughout the mines. Since there was practically no food for them except the human stools deposited in the mines, it is evident that they must make these their regular article of diet, and the rapid disappearance of the stools bears out the truth of this. In the much frequented defæcation area where some remains of old stools were found, it is evident that the accumulation of stools was so rapid that the roaches could barely keep pace with it. I have found in laboratory experiments that roaches prefer fresh to old feces, so unless the stools deposited on any one day were completely devoured before the next day, the remaining portion would be left in favour of the newly deposited supply. In the case of scattered stools these were usually devoured completely before a new supply was searched for. In consequence, very little, if any, hookworm infestation would develop on the sites of the scattered stools, while in the more frequently used places small portions of the stools would be left and the larvæ remaining in this part would be permitted to mature and cause ground infestation. I believe that this satisfactorily accounts for the relatively high degree of infection of the persons who deposited stools in such places, as remarked above.

It seemed important, however, to ascertain the fate of the helminth eggs devoured by roaches along with the feces. Probably a very high proportion of the roach droppings would be left in concealed or protected places,

or fall into crevices, where a foot would be unlikely to come in contact with them, but some would occasionally be left in places where effective infestation of the substratum would result in case the eggs were passed through the roaches in a viable condition.

To get information on this point some roaches were fed with feces containing large numbers of hookworm eggs, as well as a fair number of *Ascaris* and *Trichuris* eggs, and the droppings of the roaches subsequently collected and examined. Some of the droppings were allowed to fall on dry paper, and were collected at the end of 24 to 30 hours, while others were allowed to fall on moist blotting paper. After collection the droppings were soaked in water, made into an even suspension, and the eggs collected by Lane's D. C. F. method. Great numbers of eggs of an *Oxyuris*, nearly universally parasitic in the roaches used, were obtained in all cases. From the droppings which were collected from dry paper, and most of which had hardened and dried, a small number of hookworm eggs were recovered, but nearly all of them appeared dead or abnormal, probably from drying. From the droppings collected from moist blotting paper a small number of healthy-looking eggs were obtained. Small numbers of *Ascaris* and *Trichuris* eggs were obtained from each series. Some of the roach droppings, both dry and moist, were collected and placed on sand in a feces tin to allow the larvæ to develop. After seven days these cultures were set up for extraction of any contained hookworm larvæ by the Baermann apparatus, as modified by Cort et al. (1922). Two cultures made from about 2 mgms. each of dry or partially dry droppings yielded only two and four larvæ respectively. Another similar culture made from moist droppings from roaches fed on material containing very large numbers of concentrated hookworm eggs yielded 110 larvæ. It is evident from this that such larvæ as are passed out of the roaches with their droppings are perfectly healthy and develop readily in roach droppings on an otherwise sterile medium, but that only a small fraction of the eggs devoured are actually passed through.

To find out more accurately what happened to the hookworm eggs eaten by the roaches, a large number of eggs were collected by the D. C. F. method, recentrifuged in water, and mixed with some soft crushed banana. When a bit of this was smeared on a slide large numbers of eggs could be seen in every field under a microscope. This material was fed to some hungry roaches and was greedily devoured by them. Some of the roaches were killed and dissected a few minutes after they had eaten, and others about one and one half hours later. In both cases the crop was found distended with the crushed banana and the

hookworm eggs were apparently as numerous as before the material was devoured. Obviously the eggs were not destroyed by chewing. Up to one and one half hours after feeding none of the material had passed through the proventriculus and the intestine was practically empty. Next morning, about 18 hours later, the rest of the fed roaches were killed and dissected. The crops were now empty but the intestines were full, all the food having passed the proventriculus. The contents of the intestines were spread out on slides and carefully examined for hookworm eggs, but a prolonged search of the contents of six roaches revealed only about half a dozen eggs. It seems indisputable from this that only a few eggs succeed in passing through the proventriculus of the roach, the rest being broken and destroyed by the powerful chitinous grinding organs in the proventriculus.

One must conclude from this that, at least so far as the propagation of helminthic infections are concerned, cockroaches are very useful scavengers, and succeed in destroying the great majority of the worm eggs which they devour. Under conditions such as exist in the coal mines of Bengal they must play a very important part in controlling hookworm infection. As long as other food is withheld from them and the stools are not concentrated too much in one place, they must very largely keep the mines free from infection. In mines where rats and mice abound it would be advantageous to trap these animals in order to keep them from preying on the roaches.

CONCLUSIONS.

Surface infestation of the soil with hookworm larvæ is practically entirely stopped for about six months of the year, due to desiccation. In consequence of this break in the continuity of re-infections, hookworm infection is relatively very light in the agricultural villages of the Asansol Mining Settlement, since annually about 60 per cent. of the infection acquired during the favourable monsoon period is lost before re-infection begins again. This lessens the degree of soil infestation at the beginning of each successive favourable season, and thus the infection is kept down to a low level, in spite of defæcation habits which would otherwise favour a high degree of infection.

In the mines disused galleries, especially at the sides of streams, are used as defæcation sites. Conditions of temperature and humidity are highly favourable for the development of hookworm larvæ, but in spite of the fact that there is no desiccation, no activity of Scarabæid beetles, and no domestic animals to feed on the fæces, the stools rapidly disappear, being eaten up by cockroaches. It has been shown that when worm eggs in

fæces are eaten by roaches only a few pass through in viable condition, the rest being destroyed by the grinding organs in the proventriculus. Only where numerous stools are daily deposited in a small area are any traces of old stools to be found. Roaches, therefore, play an important part in the control of hookworm infection in mines, and should be encouraged by trapping rats and mice which prey on them. Only in stools collected in a much used place where the activity of the roaches could not keep pace with the deposition of fresh stools, was a relatively high number of hookworm eggs found. The average eggs per gram of fæces of these stools were over six times as great as in those found in scattered stools in the mine, and nearly five times as great as the average eggs per gram of 75 people living in the coolie lines on the surface.

VARIATIONS IN THE POTENCY OF DIGITALIS PREPARATIONS IN THE TROPICS (II).

By R. N. CHOPRA, M.A., M.D. (Cantab.),

MAJOR, I.M.S.,

Professor of Pharmacology,

and

PREMANKUR DE, B.Sc., M.B. (Cal.),

CAPTAIN, LATE I.M.S.,

Assistant Professor of Pharmacology.

(From the Department of Pharmacology, School of Tropical Medicine and Hygiene, Calcutta.)

In a paper published last year we pointed out that clinical observations as well as the biological and chemical assays of tinctures of digitalis show that they undergo deterioration rapidly in a warm climate such as that of India. We gave experimental and clinical data concerning a large number of tinctures, manufactured by reputed firms, which we had tested, showing that in a very short time they show a reduction of 20 to 40 per cent. in their strength. We also showed that tinctures freshly prepared from *Digitalis purpurea* leaf grown in Kashmir (Northern Himalayas) were quite active and showed at least the normal potency of a standard tincture (in some cases more) when tested by methods of biological assay as well as when tried clinically on patients. Unfortunately,

however, digitalis is not grown on any large scale in Kashmir, the specimens tested by us being grown purely for experimental purposes in a private garden. Digitalis leaf was grown in the Nilgiris at one time on a large scale but we have shown in a recent paper that its therapeutic activity as tested by laboratory methods is not great. It causes little or no slowing of the mammalian heart under experimental conditions, whilst the muscle poison effects overshadow the normal therapeutic effects when the preparations are injected intravenously. We have, however, suggested that this leaf should be given a thorough clinical trial before it is finally condemned. The muscle poison effects may not be produced when preparations made from it are given by the mouth.

Digitalis purpurea is also grown on a commercial scale in Mungpoo (Eastern Himalayas) and we have shown that, when assayed biologically, different specimens show marked variations in their activity. Some tinctures prepared from Mungpoo-grown leaf are quite active while the others are comparatively weaker. These variations, as we have pointed out, are probably due to the methods of drying and storing adopted there.

The outcome of all this is that the practitioner in this country does not know what is the strength of the preparation he is administering to his patients and is therefore faced with a great deal of uncertainty as regards the dosage he should employ and the therapeutic effects he may expect to obtain. Dr. S. C. Bose has stressed this point in his paper entitled "Clinical Studies on Digitalis in Bengal." After testing a large number of preparations on an extensive series of cases of heart failure in Calcutta he showed that none of the tinctures on the market could digitalize patients in doses of 5 to 8 drachms, as is the case in America and Europe. With most of the tinctures obtainable on the market in India massive doses of two drachms daily had to be given for 8 to 10 days before any conspicuous benefit was obtained. Dr. Bose communicated his own clinical results as well as those of biological assay obtained by us to Messrs. Parke Davis & Co., who have recently imported into this country a very powerful tincture whose strength is 50 per cent. greater than that of the ordinary tincture of digitalis of the United States Pharmacopœia. This tincture was formerly known as Digitalis Tincture No. III but has now been given the name of *Digifortis*. This preparation is free from fat, is sold in convenient one-ounce bottles and is further protected from oxidation by the use of carbon dioxide. The date of manufacture is put on each bottle and the manufacturers advise that it should not be used after twelve months after the date of manufacture. The dose advised by the

makers is 8 minims or 0.5 c.c. but we have given 30 minims or nearly 2 c.c., diluted with a little water, on an empty stomach without any discomfort to the patient or untoward effects.

Dr. Bose has tried this preparation in a fairly large number of cases of heart failure with and without auricular fibrillation and has had uniformly good results. Most of his cases could be got under digitalis effect with a total amount of 5 drachms in 5 days. Our own results on patients in the Carmichael Hospital for Tropical Diseases have been equally satisfactory.

As the existence of a good reliable preparation of digitalis is of great importance to medical practitioners in the tropics we have investigated the keeping properties of this tincture. Seven specimens of this preparation were kept at the laboratory temperature (60 to 100°F.) for periods ranging up to 20 months. These tinctures were then tested by a modification of Hatcher's cat method. The details of the results obtained are summarised in the table on p. 214.

DISCUSSION ON THE TABLE.

A perusal of the table will show that out of seven specimens of overstrength tincture of digitalis, five tinctures (Nos. 1, 2, 3, 5, and 6) kept their potency fairly well and produced reasonable slowing of the mammalian heart. Tincture No. 4, although prepared in October 1925 and assayed in March 1926, was toxic when given intravenously. It was dark greenish yellow in colour, showed a fine black sediment and did not produce any marked slowing of the heart. This may be due to defective sealing of the bottle. Specimen No. 7 was stored for nearly 20 months, i.e., 8 months over the time-limit fixed by the company after which the tincture should not be used; it showed very marked changes. This tincture on dilution was nearly black in colour, showed a large amount of precipitate and was toxic when administered intravenously for purposes of assay. To avoid confusion it may be pointed out here that tinctures which deteriorate and become toxic intravenously, do not produce any poisonous effect when administered by the mouth, though of course they produce little therapeutic action.

After examination of a large number of digitalis tinctures exposed to a warm climate, we have been able to evolve a rough but practical test to enable the practitioner to judge whether a particular preparation is likely to be active or not. Most of the good tinctures when diluted with nine parts of physiological saline or water have a light uniformly opalescent green or yellowish green colour. If on dilution the solution is blackish and contains fine black particles floating in it the probability is that the tincture has deteriorated. Some of these preparations on

Biological Assay of Overstrength Tinctures of Digitalis.
(Digifortis, Parke Davis & Co.)

No. of Tincture.	Physical characters of dilute solution (1 in 10).	Date of manufacture.	Date of Assay.	No. of c.c. equalling 1 c.c. of standard tincture.	Comparative potency with standard tincture, per cent.	REMARKS.
1.	Light greenish yellow, opalescent.	January 1925	15th February 1926.	0.7 c.c.	142.9	
2.	Ditto.	Ditto.	17th February 1926.	0.835 c.c.	120.4	
3.	Ditto.	Ditto.	18th February 1926.	0.667 c.c.	151.5	
4.	Dark greenish yellow with some fine black precipitate.	12th October 1925.	4th March 1926.	0.545 c.c.	183.4	Toxic intravenously, but no poisonous effect when given by the mouth.
5.	Greenish yellow, slightly opalescent.	16th June 1925.	8th March 1926.	0.725 c.c.	137.9	
6.	Yellowish green, opalescent.	Ditto.	23rd March 1926.	0.733 c.c.	137.0	
7.	Blackish fine particles.	4th August 1924.	24th and 25th March 1926.	0.438 c.c.	228.3	Toxic intravenously, but no poisonous effects when given by the mouth.

careful examination show a fine sediment settled at the bottom of the bottle.

It would appear from both experimental and clinical data which we have collected, that making allowance for the effect of the climate and the delay in use of the preparation in India after manufacture which must necessarily occur, there still remains adequate potency in this preparation and it would be possible for the patients to be digitalized with the usual doses of 4 to 6 drachms in 4 to 6 days with fresh specimens of this tincture, which is the aim of the practitioner. The importance of using only the samples which are within the stated period of twelve months is obvious from the assay of tincture No. 7.

THE TREATMENT OF SYPHILIS BY BENZO-BISMUTH.

By S. B. SURTI, F.R.C.S.I., D.P.H. (Irel.),
Civil Surgeon, Gulbarga.

DURING my three years' practice in Gulbarga District I have had occasion to employ several drugs in cases of syphilis, including the following, with varying success:—

- (1) Pulv. hydrarg. cum creta with Dover's powder orally.
- (2) Liquor hydrarg. perchloridi cum potass. iodidi orally.
- (3) The Anglo-French Drug Company's preparation "Mersalv" by inunction.
- (4) Triple iodide solution consisting of ammonii iodidi, iodide of mercury, and arsenic iodide by intravenous injections.
- (5) "Supsalvs" by rectal administration.
- (6) Neosalvarsan in varying doses, either by intravenous or intramuscular injections.
- (7) Sulfarsenol in graduated doses either by subcutaneous, intramuscular or intravenous injection.
- (8) Last of all "Benzo-Bismuth" (Anglo-French Drug Co.'s preparation) by injections, either subcutaneously or intramuscularly.

With increasing experience in the treatment of syphilis, I feel less and less inclined to administer mercurial preparations except in the form of triple iodide solution, 7 c.c. administered intravenously once a week, but the main disadvantage in using this drug is that it has got to be given always through the venous channel, and the slightest infiltration in the subcutaneous tissues is followed by excruciating pain with the result that the patient never returns for a further course of treatment. Moreover it has got a tendency to produce stomatitis of a severe type. "Mersalv" injections can only be relied upon when combined with a course of "Supsalvs" administered per rectum. Unfortunately, the price being prohibitive, this line of treatment is out of the question for hospital patients.

From among the arseno-benzol series I have found sulfarsenol to be a sovereign remedy in all stages of syphilis, especially when complicated with either gonorrhœa, leprosy, filariasis or malarial fevers; but even this medicine, so far as the poor class of patients is concerned, is beyond their reach, as each course of treatment costs not less than Rs. 20 or so.

Only recently I have had occasion to give a fair trial to a soluble organic salt of bismuth called "Benzo-Bismuth". The results obtained from its administration are extremely encouraging and nowadays I have been using it extensively among my patients with great success. The first case that I treated with this drug was one of secondary syphilis with a ring of condylomata around the anal orifice and a venereal wart on the lower lip. After receiving a course of 3 injections intramuscularly, within one week, the patient felt himself absolutely a different man; the condylomatous growth in the anal region subsided some 75 per cent. and the warty growth on the lip shrivelled up and was removed ultimately by ligaturing the pedicle, leaving a smooth surface flush with the mucous membrane.

The second case was that of an adult about 20 years old with a serpiginous ulcer involving the left ala nasi, of one month's duration, treated in a Taluka dispensary as a simple ulcer with antiseptic dressings. As soon as the patient was brought to my notice, the affection was diagnosed as one of venereal origin and the patient was given a series of Benzo-Bismuth injections both subcutaneously and intramuscularly. After a course of 5 injections (2 subcutaneous and 3 intramuscular), the ulcer completely healed up within three weeks and with the exception of a little deformity that was left on account of the margin of the left ala having been eroded, no trace of the disease was discernible.

The third case was that of an individual suffering from huge rupial eruptions all over the back, and big gummatous nodules on both

legs and ankles (with the left leg presenting an elephantoid appearance), and ulcers on both arms. This patient made a speedy recovery after receiving 5 injections within a fortnight.

The fourth case was that of a woman aged about 28 years, who came to the hospital with the whole of the left leg studded with innumerable sinuses, discharging foul stinking pus and full of maggots. There was also a gummatous node, about the size of a duck's egg on the middle of the right shin. The condition was of 6 months' duration. This woman also recovered very rapidly; the node completely disappeared and the foul septic condition on the left leg entirely dried up, leaving behind healthy scar tissue after the patient's receiving a course of 8 injections within one month.

Having run short of the stock I had no occasion to try this medicine on more cases, but the few cases that I have treated with highly satisfactory results justify me in advocating its use in purely syphilitic cases not complicated with either gonorrhœa or leprosy, in which latter class of cases the use of sulfarsenol is a *sine quâ non*.

With a view to bring about complete cure from a serological point of view, and in order to maintain complete immunity from the disease it would be best to follow carefully the directions given in the literature that accompanies each box containing five ampoules of the Benzo-Bismuth together with a similar number of ampoules containing sterilized neutral solvent. From my personal experience I find the main advantages of using this preparation to be:—

- (1) The small quantity that is injected, not exceeding 1.5 c.c.
- (2) The ease with which the drug is administered either intramuscularly or subcutaneously.
- (3) The painlessness after injection.
- (4) The uniformity of dosage.
- (5) The comparative cheapness.
- (6) No liability to toxic symptoms.
- (7) Complete solubility of the drug in a watery medium without leaving any particles in suspension.

EXTERNAL MEDICATION IN LEPROSY.

By Dr. E. MUIR, M.B., Ch.B., M.D., F.R.C.S.,
Leprosy Research Worker, Calcutta School of
Tropical Medicine.

LEPROSY is a disease which affects the skin more than any other part of the body. The corium is affected directly by the presence of lepra bacilli in its cells and intercellular spaces; and the epithelium is affected indirectly through the nerves and by reason of the

condition of the corium. It is natural, therefore, that we should expect benefit from external medication applied to the skin.

The visible lesions of leprosy may conveniently be divided into three classes, each class being typical of a particular stage of the disease.

(1) Lesions, one or more in number, spreading radially from the centres of infection. These generally show a raised, erythematous, spreading margin, raised in proportion to the grossness of the lesions; while the centre, beginning with a small umbilicated depression, is flatter than the margin, and shows, more or less, the characteristics of a scar. In dark skins such lesions are more or less depigmented in the central area and sometimes in a narrow circumferential band which spreads in advance of the erythematous margin.

(2) These spreading areas tend to coalesce and their spreading, erythematous margin tends to die down, so that large areas of tissue, which have more or less the nature of a scar, are left. This character of a scar is not always complete as the infection may spread from the more superficial layers of the corium, which are first affected, to the deeper layers. Nodulation may be superimposed on such lesions when conditions favour the multiplication of bacilli in them.

(3) The third is the glove-trophic type and is due to contraction of the newly-formed fibrous tissue around the axis-cylinders in the long nerve trunks, which leads to various trophic changes in the extremities, such as loss of sensation, wasting of the small muscles of the hands and feet, claw-hand, ulceration and shortening of the fingers and toes, perforated ulcers, etc.

Reference will be made later to these three different types of lesions in describing various methods of external medication.

Treatment in leprosy may, for convenience sake, be divided under three divisions:—(a) means which will cause improvement of the general health of the patient, (b) special remedies which may be given by the mouth or by injection, (c) external medication. The present paper will deal with the last of these.

It may be convenient to divide external medication under the following heads:—

1. Baths, which may be hot or cold, preferably hot followed by cold; they may be given as plain baths or baths containing such medicaments as soda, mustard, etc.

2. Friction accompanied by inunction. Both of these have for their object the flushing of the skin, the strengthening of the muscles and improvement of the general health of the body, while they probably tend to set free minute doses of toxins and produce a certain limited amount of immunity.

3. Caustics.

4. Surgical procedures.

I propose to limit the present paper to the consideration of the last two.

Caustics.—Many remedies have been used to cause that useful, though difficult to explain, condition called counter-irritation. Pure carbolic acid, carbon dioxide snow, various juices of plants and even the thermo-cautery have been used with a greater or less amount of benefit, while the natives of some of the South Sea Islands burn the skin around the lesions with a burning cigarette end; in fact, the number of counter-irritants which have been used is practically innumerable.

Recognising that there is a certain amount of benefit to be derived from counter-irritation, however it is brought about, we tested several different methods, and have found the most effective and the most easily controlled to be trichloroacetic acid dissolved in water. We apply it in three different strengths:—a 1 in 1 solution, which is applied to the centre of large thick nodules; for painting on the face it is convenient to use a 1 in 5 solution so as to avoid all danger of over-cauterisation; and a 1 in 3 solution, which is the most generally useful and may be painted on to any of the lesions of the first two types described above. Cotton-wool on a glass rod or a piece of bamboo is used as a brush, which is dipped in the solution and pressed against the sides of the bottle so that too much does not remain on the brush; the solution is painted rapidly over the lesion or lesions selected for application and allowed to dry. As drying takes place a slightly white appearance should be seen, as if the surface of the skin had been sprinkled with a white powder; if this does not appear on the drying of the solution, a second painting is required or even a third, but it is necessary to wait each time until the solution has dried. Care must be taken that either too strong a solution or too much of it (by having the brush too wet) is not applied to the wound, in which case the skin would appear uniformly white, as this may be followed by ulceration or by keloid formation. If the right amount of solution has been applied, the white, powdery appearance will give place, in a few hours, to black discoloration; and the black, burnt epithelium will separate in a few days, leaving a red surface which soon shows either hyperpigmentation, or depigmentation followed by hyperpigmentation.

This application may be repeated after 10 days. It is convenient, when injections are given twice a week or thrice in 10 days, to divide all the areas in the body requiring counter-irritation, into three parts, one part being painted on each injection day. The application of trichloroacetic acid causes a burning sensation for about two minutes; but

in spite of this, patients who have seen the results produced, insist on having it done.

The effects of the application of trichloroacetic acid are easily demonstrated by painting one side of the body—say of the face—while leaving the other side unpainted. This is shown in the photographs in a case in which lesions were equal on both sides to begin with (see Figs. 1, 2 and 3).

Fig. 1—Patient before treatment.

Fig. 2.—Side of face of same patient as Fig. 1, which has not been painted with caustic. Patient has undergone treatment by injections for a few weeks.

Fig. 3.—Other side of same face which has been painted with trichloroacetic acid repeatedly. The lesions were equal on both sides to begin with.

How the cauterisation acts it is difficult to say, but it seems to light up a local reaction which causes the formation of granular and resistant forms of the bacilli and also diminution in the numbers of or complete disappearance of the bacilli.

The great advantage of this form of application is that it can be absolutely regulated. More of the acid is required when the surface of the patient's skin is more alkaline or has more oil on it; but the powdered, white appearance described above is in every case a sure index to the amount of application required.

SURGICAL TREATMENT OF NODULES AND REDUNDANT SKIN.

(a) *Removal of early Nodules.* In cases in which there are only one or two nodules and no other marked lesions in the body, it is well to remove the nodule with the knife. This may generally be done with local anæsthesia. Even though the whole of the infection is not removed with the nodule, the plastic process set up by the operation causes entire disappearance of the lesion, only a scar being left; this is, of course, provided that the general resistance of the patient is good, otherwise such procedures have little chance of arresting the disease.

(b) *Trimming the Auricle of the Ear.* The nodular, pendulous, elephant-like ears of the advanced leper are well known; the disfigurement is very characteristic. But this condition can be improved very easily by a

simple surgical procedure. A curved clamp, such as that prepared for me by Messrs. Down Bros., (see illustration) may be used. It is applied to the auricle so that the part to be removed is external to the convexity of the clamp blade. If a shape slightly different from the curve of the clamp is required, this may be attained by pulling slightly upon the auricle before tightening up the clamp. Before applying the clamp, the ear should be cleansed and iodine applied. When the clamp has been carefully applied and tightened, the projecting skin is removed either with a pair of scissors or with a knife, and the raw surface is painted with pure carbolic acid. The clamp may be removed at once and dry cotton-wool applied; there is, as a rule, no bleeding and no bandage is necessary. Due to the deep analgesia of the part and deadening effect of the clamp, it is seldom necessary to use any anæsthetic, and patients seldom object to the procedure; indeed, when they have seen the results of it in other patients, they are generally anxious to have it done to themselves. Here, again, the benefit is not limited to the amount of redundant skin which has been removed; the plastic process causes progressive improvement for some days after the operation, and the whole appearance of the patient is often changed for the better, (see Figs. 4 to 8).

(c) *Surgical procedure in acute leprosy Neuritis.* There are few conditions more painful in leprosy than acute neuritis, which often accompanies a reaction during the course of the disease, especially when the patient has had his general resistance lowered by some intercurrent cause. We have tried electric treatment, ionisation and various internal

Fig. 4.—Ear before trimming.

Fig. 5.—Clamp applied and ear being trimmed.

Fig. 6.—After trimming and applying pure carbolic; clamp still applied.

medicines with only temporary relief; but, when the disease is confined to one nerve, as it very often is, a very simple surgical operation will remove the pain, cause considerable reduction in the swelling of the nerve and marked lessening of the anæsthesia and other nerve symptoms in the parts supplied by the nerve.

After applying local anæsthesia by infiltrating subcutaneously with $\frac{1}{2}$ per cent. eucaine or novocaine with a small quantity of adrenaline,

Figs. 7 & 8.—Effect of ear-trimming is seen by comparing two photographs.

Fig. 8.

an incision is made 3 or 4 inches in length over the affected nerve and the sheath is isolated from the surrounding tissue to the extent of

about two inches in front and one inch behind the nerve: (see Fig. 9). The wound

Fig. 9.—Scissors passed under thickened ulnar nerve.

is then sewn up and dressed. If the operation is done in the arm, which is the most common seat of this condition, the arm should be kept in a sling. The results of the operation are immediate cessation of the agonising pain, which the patient may have been suffering from for many days; reduction in the size of the nerve, which very often is $\frac{3}{4}$ inch in diameter; and restoration, to a certain extent, of the function of the nerve. When leprous infiltration of a nerve has gone on to form a nerve abscess, a condition which is not at all uncommon, similar relief is given as a rule by the opening and drainage of the abscess.

THE SEROLOGICAL ANALYSIS OF BLOODSTAINS IN CRIMINAL CASES. (ILLUSTRATIVE CASES.)

By

R. B. LLOYD, M.A., M.B., B.Ch.,

MAJOR, I.M.S.,

Imperial Serologist.

IN this article it is proposed to describe some illustrative cases of bloodstains received in connexion with criminal trials, which have been analysed by serological methods in this department, shewing the results they have yielded. As is well known, until recent years the utmost that could be done analytically in a bloodstain case was to inform the Court that the bloodstain was or was not mammalian in origin. Apart from accidental factors it was never possible to determine that any given bloodstain was human. An interesting case in which an accidental factor did supply

the clue is reported by Bose (1) who in one case found embryos of *Filaria bancrofti* in a bloodstain, and as this is exclusively a human parasite this lucky chance enabled a positive identification of human blood to be made. Cases of this kind are naturally curiosities. Serological examination by means of specific precipitin antisera on the other hand enables precise identification of the origin of a bloodstain to be made in every case, given a stain not too minute and in reasonably good condition. These tests therefore provide information in legal cases which is not obtainable in any other way. The number of bloodstain analyses made in this department is very large, and during the last six years one has examined personally over 11,000 cases comprising an examination of some 35,000 articles from all parts of India and Burma. Over 90 per cent. of the bloodstains have been identified as to origin. In a small percentage the stains have undergone chemical changes due to the influence of water, chemicals, lime, &c., and in a few cases the stains are too intimately mixed with gross dirt or other foreign matter to permit of identification. In a few cases too, despite the amazing sensitiveness of the test—it can be carried out with one drop of a thousandfold dilution of blood—the stain is too small for identification. Over 80 per cent. of the bloodstain cases received are murder cases, and the majority of the bloodstains have been proved to be human. Nevertheless there are many interesting exceptions, and many false charges are thus brought to light. As will be seen from the cases which follow more than one kind of blood is frequently found in a stain. It is always a matter of considerable interest to discover how this has been effected. It is much to be desired that some exact method of determining the age of a bloodstain will be devised, for then we shall perhaps be in a position to determine which was the original stain and which was afterwards added. It is a remarkable fact that of those cases in which human blood is suspected, by far the largest number of non-human bloodstains—and therefore presumably of false charges—occur in charges of rape.

It may be of interest to note the type of articles which are received for analysis:—clothing of all kinds, knives, grass cutting choppers, sickles, earth, stones, leaves, twigs, pieces of wood and articles of jewellery are among the items most commonly received. The very large number of specimens of earth is especially noteworthy. This is natural as the population of India is largely rural. From Burma come powerful *dahs* and *dahshes*: swords from the Punjab and Rajputana: kukris from the hill districts. Buckets, lamps, coins, currency notes, water, firearms, bullets, books and papers are articles less frequently received.

The bloodstains may be large or small, fresh or old, sometimes highly stinking from decomposition, especially when packed wet during the monsoon season. The stains may be invisible to the naked eye, being concealed by rust, fruit juices, &c. In many instances attempts have obviously been made to conceal or destroy the stain by washing, burning or the addition of ink, paint, oil and the like. With the exception of certain chemicals which destroy the serum proteids, I know of no substance upon which a bloodstain cannot be identified as to origin; though special precautions are necessary in the case of leather and certain other articles.

In addition to bloodstains, other tissues of the body such as bones—if not too dry,—portions of muscle, skin, &c., can be identified as to human origin or not. Only very minute quantities of material are required: so small that the fragments of tissue could not possibly be identified by other means. The tests can therefore be applied to detect fraudulent sales of meat, e.g., horse meat for beef. They may also be utilised in the enforcement of game laws.

Serological tests can also be applied to the identification of proteid-containing secretions and excretions such as milk, semen and albuminous urine.

By serological tests we recognise the presence of proteid of a particular species: the method is not by itself a test for blood; and before serological tests are applied to blood solutions the presence of blood must be confirmed by any of the tests characteristic of hæmoglobin, of which microspectroscopy is by far the most suitable for bloodstains.

The following are some cases analysed in this department, classified according to the nature of the offence:—

Murder and Culpable Homicide Cases.

1. In a case from Madras Presidency miscellaneous articles and a dagger were forwarded for examination. Some of the articles were found to be stained with human blood, and many were found to be stained both with human blood and with the blood of a ruminant animal. The dagger, however, the weapon with which the offence was supposed to have been committed, was found to be stained with bovine blood alone.

2. In a murder case some earth, a piece of mat, and some straw were received from Bihar for examination as to human blood. The mat was found to be stained with the blood of a bird, while both the earth and straw were proved to be stained with the blood of a goat or sheep. Human blood was absent from all three items.

3. In a murder case three shirts and a handkerchief were received from Burma for examination as to human blood. The stains on all four articles were found to be due to

the blood of a ruminant animal, and human blood was absent.

4. In a case of dacoity (gang robbery) with murder some bloodstained earth was received from Madras Presidency. Fowl's blood was suspected. The stains on the earth were proved to be those of the blood of a bird (probably fowl).

5. In a case of attempted murder a knife was received from the Punjab for examination for human blood. The stains on the knife were found to be due to the blood of a sheep or goat and human blood was absent.

6. In a murder case from the Central Provinces a bloodstained stick was received for examination for human blood. The bloodstains were found to be due to bovine blood and human blood was absent.

7. In a murder case from the North West Frontier some bloodstained matting and sacking were received for examination as to the presence or not of human blood. It was suspected that mare's blood had been afterwards added to the sacking. The matting was found to be stained with non-mammalian blood, and the sacking was found to be stained both with horse's blood and with the blood of a ruminant animal, human blood being absent from both articles.

8. An axe was received in a murder case from the Central Provinces suspected to be stained with human blood. The blood present was proved to be bovine and human blood was absent.

9. An axe and two *dhoties* were received in a murder case from the Central Provinces. The axe and one *dhoti* were not bloodstained. The second *dhoti* was found to be stained with the blood of a bird (probably fowl) and human blood was absent.

10. Some earth and a cloth were received in a murder case from Madras Presidency. The earth was proved to be stained with human blood. The cloth, however, was proved to be stained with the blood of a ruminant animal.

11. Three specimens of earth and three specimens of leaves were received in a murder case in Bengal with a request for report as to whether the bloodstains thereon were caused by human or fish blood. One specimen of earth was not bloodstained. The remaining five specimens were stained with human blood.

12. In a case of murder a chopper and two axes were received from Bombay Presidency. One axe was proved to be stained with human blood. The chopper was stained with the blood of a ruminant animal. The second axe, however, was stained both with human blood and with the blood of a ruminant animal.

13. In a murder case a large number of articles were forwarded for analysis of the bloodstains thereon. All the articles were found to be stained with human blood. One

of these articles was a bullet on the base of which bloodstains were present which were proved to be human. The point of the bullet was depressed to form a cup: within the small cup was a minute fragment of hard substance which appeared to be bone. On removing this, a portion free from blood was obtained; and it yielded sufficient extract to permit of its identification as human by serum tests. The fragment was identified by the Government Pathologist as bone. The proof that the fragment was human bone was important evidence in the case.

14. A shirt and some wood shavings were received in a murder case from Burma for report as to whether the bloodstains were human. The stains on the shirt were proved to be due to the blood of a ruminant animal, while those on the shavings were non-mammalian blood; human blood being absent from both.

15. In a murder case a knife and billhook were forwarded from Madras Presidency for identification of the bloodstains thereon. Both these articles were proved to be stained with the blood of a ruminant animal, and human blood was absent.

16. In a murder case a knife and fourteen articles of clothing were received from Madras Presidency. The articles of clothing were all proved to be stained with human blood. The knife, however, the weapon with which the murder was supposed to have been committed, was found to be stained with non-mammalian blood.

17. Bloodstained cuttings from a shirt were forwarded in a murder case for report as to whether the blood was human or from a goat. The stains were proved to be due to the blood of a sheep or goat and human blood was absent.

18. Some sacking, a shirt, some string, earth, a spade, and some rags were received in a murder case. The rags were found to be stained both with human blood and with the blood of a sheep or goat. The remaining five items were stained with human blood alone.

19. A bloodstained stone was received in a murder case. The blood was proved to be bovine and human blood was absent.

20. Some earth and leaves were received in a murder case from Bihar. Both items were found to be stained with the blood of a ruminant animal, and human blood was absent.

21. A cloth and two specimens of earth were received in a murder case from Bihar. One specimen of earth was found to be stained with human blood. The cloth and the second specimen of earth were, however, found to be stained with non-mammalian blood.

22. In a murder case a sheet and three shirts were received from the Punjab. One of the shirts was found to be stained with

the blood of a ruminant animal. The remaining three garments were stained both with human blood and with the blood of a ruminant animal.

23. Four pieces of bone were received in a murder case from the Punjab for identification by serum tests as to whether they were human or not. All four pieces of bone were proved by serum tests to be human.

24. A rope and two specimens of earth were received in a murder case in Bengal. The rope and one specimen of earth were found to be stained with the blood of a bird, probably fowl, and human blood was absent. The second specimen of earth was stained with human blood alone.

25. In a murder case from Bihar some cloth cuttings, some straw and a knife were received for identification of the bloodstains thereon. The cloth cuttings and the straw were proved to be stained with human blood. The stains on the knife reacted negatively with antihuman serum. On making a microscopical preparation of these, the erythrocytes were seen to be of extremely small size. This suggested that the stains were those of the blood of a sheep or goat as the erythrocytes of these animals are approximately 4.5μ in diameter. The blood was afterwards proved by serum reactions to be that of a sheep or goat.

26. In a case of murder in Bihar two pieces of wood were forwarded for identification of the bloodstains thereon. The stains on one piece of wood were those of the blood of a fowl, while the stains on the other piece of wood were those of a ruminant animal. Human blood was absent from both.

27. In a murder case from Bihar an axe and a piece of wood were received for identification of the blood thereon. The axe was found to be stained both with the blood of a bird, probably fowl, and also with the blood of a ruminant animal. The stains on the wood were too much disintegrated for identification.

Rape Cases.

28. Some bloodstained cuttings from a *dhoti* were received in a rape case in Bengal. The bloodstains were found to be those of a bird, probably fowl, and human blood was absent.

29. Bloodstained cuttings from a woman's garment and other articles were forwarded in a rape case. From the large extent of the stains on the garment and the fact that they were chiefly on the outer side, it appeared unlikely that they were due to rape; and it was suspected by the sender that the blood was probably not human. The bloodstains however were all found to be human, and no other blood could be detected as present in addition.

30. A *sari* was received in a rape case from Bombay Presidency for identification of the

bloodstains thereon. The stains were proved to be due to the blood of a bird and human blood was absent.

31. A pair of bloodstained trousers was received from the United Provinces in a case of alleged rape for report as to whether the bloodstains—if found to be human—were menstrual or not. The stains on the trousers were found to be those of the blood of a ruminant animal, thus showing that the stains whether resulting from accident or design had not been caused by the act of rape.

32. Some rags were forwarded in a rape case from Burma for determination if the bloodstains were human. The bloodstains found thereon were proved to be due to the blood of a ruminant animal and human blood was absent.

33. Two portions of the same *dhoti* were forwarded by a Chemical Examiner in a rape case. One portion was bloodstained and the stains were proved to be due to human blood. The Chemical Examiner had detected semen in a second portion, and the seminal stains were proved by serum reactions to be human semen.

34. A *dhoti* was received in a rape case from the United Provinces. The bloodstains thereon were proved to be non-mammalian. From the microscopical appearances this blood was probably either fish or amphibian.

35. Trousers were received from the United Provinces in a rape case for report as to whether the blood, if human, was menstrual or not. The trousers were found to be stained with the blood of a ruminant animal.

36. Some bloodstained pieces of pyjama were received in a rape case from the North West Frontier Province. The blood was, however, found to be non-mammalian.

37. Two cloths were received in a rape case. One cloth was found to be stained with human blood. The other cloth was proved to be stained with the blood of a bird (probably fowl).

38. A bloodstained *sari* was received in a rape case in Bengal. The *sari* was proved to be stained both with human blood and with the blood of a ruminant animal.

39. In a rape case a woman's garment was forwarded by a Chemical Examiner, who had detected semen on it. Information was required as to whether the semen was human or not. The garment was proved by serum reactions to be stained with human semen.

Theft and House-Breaking Cases.

40. In a theft case a shirt was received from Burma for examination for goat's blood. The stains on the shirt were found to be due to human blood and goat's blood was absent.

41. In a theft case a *sari*, some earth and a towel were received from Bihar for examination for human or goat's blood. The stains on the towel and on the earth were proved to be due to goat's blood, and human blood was

absent. The stains on the *sari* were too small for identification.

42. In a theft case a *lungyi* and coat were forwarded for examination as to goat's blood. The stains on the *lungyi* were proved to be due to goat's blood, while those on the coat were found to be human blood.

43. In a case of causing hurt while committing robbery, a shirt and a pyjama were received from the North West Frontier for report as to the nature of the bloodstains thereon. The pyjama was found to be stained with the blood of a fowl. The shirt however was stained both with human blood and with the blood of a fowl.

44. A coat, a sheet, and a piece of rope were forwarded from the Punjab in a case of robbery for identification of the bloodstains thereon, which were suspected to be those of the blood of a sheep. The bloodstains on all three items were proved to be due to the blood of a sheep or goat.

45. A *dah* and a piece of bamboo were forwarded in a case of house-breaking for identification of the bloodstains thereon. The bamboo was found to be stained with human blood, while the *dah* was stained with non-mammalian blood. Embedded in the clot on the *dah* were fibres which were identified as fragments of the feathers of a bird. Presumably therefore the *dah* had been used to kill a bird, and the non-mammalian bloodstains and the feathers which were found together arose in this way.

Animal-Wounding Cases.

46. Some pieces of rope, a dagger, three axes, a piece of basket and two pieces of wood were received in a cow-killing case from an Indian State. One of the pieces of wood was found to be stained with the blood of a ruminant animal which could not be further differentiated. The remaining articles were found to be stained with bovine blood.

47. Some bloodstained earth was received from a Veterinary Assistant in the Bombay Presidency for report as to whether the bloodstains thereon were those of an ass. The bloodstains on the earth were proved to be of equine origin (horse, mule or ass).

48. In a case from the North West Frontier a sentry fired during the night at some object. The next morning bloodstains were found on the ground, and some bloodstained paper and dark powder were forwarded to this department by order of the Brigade Commander who desired to know if the bloodstains were human or not. The blood was proved to be of equine origin (horse, mule or ass).

49. In an animal-wounding case a cloth was received from the United Provinces suspected to be stained with horse's blood. The bloodstains on the cloth were proved to be of equine origin (horse, mule or ass).

50. In a case of animal-wounding which was tried by court martial, a bayonet, belt and two khaki coats were forwarded for examination as to the presence of mule's blood. The bloodstain on one of the khaki coats was too small for identification of its origin. On the remaining three items equine blood was detected (horse, mule or ass). This analytical result was important evidence in the case as it connected the blood found upon the prisoner's bayonets, &c., with wounds received by some Government mules.

51. In an animal-maiming case a mud pot was received for examination for sheep's blood. The stains found thereon were proved to be due to the blood of a sheep or goat.

52. In a cattle-maiming case from Bihar a knife and a cloth were received. The bloodstains on both articles were found to be due to bovine blood.

Miscellaneous Cases.

53. Some bloodstained earth was received in a case of defiling places of worship. The blood was suspected to be cow's blood. The bloodstains on the earth were proved to be bovine.

54. In an unnatural offence case a cloth cutting was forwarded from Sind. The bloodstains thereon were proved to be of non-mammalian origin.

55. A knife, some string and a cloth were received from the Punjab in an assault case. The knife and the string were proved to be stained with the blood of a ruminant animal. The cloth however was stained with human blood.

56. In a case of concealment of delivery a petticoat and cloth were received for identification of the bloodstains thereon. Both articles were proved to be stained with human blood. Subsequently other stained portions of the same two articles were forwarded by the Chemical Examiner for report as to whether stains of human milk were present. The Chemical Examiner reported that he had found fat and a reducing sugar in the stains from which he concluded that the stains were those of milk. Serum reactions proved that the stains were of human origin. The stains were therefore obviously those of human milk.

57. In an unnatural offence case bloodstained earth and cloth cuttings were received from Sind. The earth was found to be stained with human blood. The cloth cuttings however were found to be stained with the blood of a ruminant animal.

58. In a case of rioting two specimens of bloodstained earth were received for examination. The bloodstains were suspected to be either human or those of a rat. The stains on one specimen of earth were too much disintegrated for identification. The second specimen of earth was found to be stained

both with human blood and with the blood of a rat.

59. In a case of assault by means of an instrument used for shooting, two arrows were received for report as to whether the bloodstains thereon were human. The defence was that the bloodstains were those of a deer which had been killed in hunting. The blood was however proved to be human and deer's blood was absent.

60. In a case of alleged unnatural offence with a she-calf, a pyjama, two specimens of earth, some straw, and a leaf were received from the Central Provinces. The pyjama was found to be stained both with human blood and with the blood of a ruminant animal. The remaining four items were stained with ruminant blood alone.

61. Three specimens of earth, a cloth, a spade and a brick were forwarded for report as to whether the bloodstains were human blood or goat's blood. The brick was found to be stained with the blood of a sheep or goat. The spade was found to be stained both with human blood and with the blood of a sheep or goat; while the remaining four items were stained with human blood alone.

62. In a case from Bombay Presidency a *dhoti* and a *langoti* were received for examination for pig's blood. Both the articles were found to be stained both with pig's blood and with human blood.

63. In a case from Madras Presidency some skin with hair was received for identification. The tissue was proved by serological tests to be human.

64. In a case from Madras Presidency a bloodstained cloth was received with the information that bull's blood was suspected. The stains on the cloth were proved to be due to human blood and bull's blood was absent.

65. Some bloodstained rags were received in a case of sodomy. The father of the boy victim stated that he had used the rags to wipe the blood from the rectum of his son. The stains on the rags however were proved to be due to the blood of a bird.

66. In a case from Madras Presidency a cloth and two yokes were received. The stains on the cloth were too much disintegrated for identification. One of the yokes was stained with human blood, while the other was stained with the blood of a ruminant animal. The ruminant bloodstain on one of the yokes probably arose from the galling of the animal by the yoke. Ruminant bloodstains which have probably been caused in this way are frequently found.

67. A chopper was received on which human blood was detected. Firmly embedded in the bloodstain were hairs which were identified as human hair. The presence of human hair in a bloodstain strongly suggests that the bloodstain is human, but this is not

necessarily the case. Moreover the bloodstain may be derived from more than one kind of blood. Conversely, the finding of human blood suggests that the hair—which may be too dark in colour to identify microscopically—is human hair, but again this is not necessarily the case; though no doubt the finding of the hair of one species embedded in the clot of the blood of another species would be something of a curiosity. Loose hairs are of course of no evidential value as they may have fallen from anywhere.

68. A Civil Surgeon forwarded some dried meat for identification in connection with a suspected fraudulent sale of meat. The meat was found to be that of an equine animal, probably horse meat.

SOME OBSERVATIONS ON THE BLOOD SUGAR AFTER TREATMENT WITH INSULIN IN DIABETES.

By LALMOHON GHOSHAL, I.M.S.,

Demonstrator of Physiology, Medical College, Calcutta.

IN cases of diabetes which are treated with insulin successfully the blood sugar comes down generally to 0.1 or 0.12 per cent. In some cases it has been noticed to come down to 0.06 per cent. This was in a case of diabetes which was treated in hospital; and even with such a low percentage of blood sugar there was found no alarming symptom whatsoever.

This naturally brought to my mind the question, what happens to the blood sugar? whether it is present in loose combination with the proteins or whether it is chemically combined with the proteins of the blood. Estimation of blood sugar by the Folin Wu method in the ordinary way brought about the same findings, so it is not in loose combination with the proteins. It must therefore be in chemical combination with the protein matter of the blood. I therefore tried to hydrolyse the blood with 5 per cent. HCl but with no result. Then I tried two per cent. H_2SO_4 to hydrolyse the blood sugar but unsuccessfully. This was probably due to the delicate nature of the carbohydrate combination and consequent metamorphosis into some other product by the strong acid. Finally I hit on the idea of hydrolysing the sugar by very weak acid.

I adopted the following method:—

1 c.c. of blood was taken and diluted with 7 c.c. of distilled water and then 1 c.c. added of 2/3 $NH_4 SO_4$, as used in the Folin Wu method to precipitate the proteins. I then put this product in a water-bath at $80^\circ C.$ for one hour.

Then the blood sugar was estimated; and to my astonishment the blood sugar was always found to increase. Thus when the blood sugar after a complete insulin course was 0.1 per cent. it was found by this method to be 0.2 per cent. This method generally succeeded only when there was no sugar in the urine and when the blood sugar was on a low level such as 0.1 per cent. or below it. Above this level this process did not succeed, neither did it succeed in normal cases nor in untreated cases. This puzzled me and I hit on the following idea. I thought that when hydrolysis with acids succeeds in some cases in bringing out the actual amount of sugar from the masked amount, digestion of the blood with pancreatin will certainly give a better result both in normal cases as well as in diabetic blood; so also in masked cases too.

Working on this idea I digested the blood with pancreatin and the results were uniformly found to be higher than as originally investigated by the Folin Wu method.

I adopted the following method:—

I took one c.c. of blood and diluted with 7 c.c. of distilled water; added 0.1 gm. of pure pancreatin (Merck's) and incubated for one hour. The sugar of the blood was then estimated by the Folin Wu method as usual. The results obtained from this method are as follows:—

Normal persons:—(taken from students' blood).

	Blood sugar by the Folin Wu method.	Blood sugar on digestion with pancreatin and by the Folin Wu method.
	per cent.	per cent.
1.	0.12	0.18
2	0.14	0.18
3	0.1	0.16
4	0.13	0.19
5	0.12	0.16
6	0.14	0.2
7	0.1	0.16
8	0.12	0.16

Thus we see that in every case there is increase in the blood sugar when the blood is digested with pancreatin. This also shows that the degree of blood sugar that we are accustomed to regard as normal is higher by this method. This has a very important bearing in diabetes, which we will consider later. In none of these cases was there sugar in the urine.

The blood sugar in cases of diabetes was also estimated by this method and the results were surprisingly high in every case.

The following table will show this:—

Case of diabetes	Blood sugar by the Folin Wu method.	Blood sugar on di- gestion with pan- creatin and by the Folin Wu method.
	per cent.	per cent.
1.	0.22	0.36
2.	0.26	0.36
3.	0.3	0.5
4.	0.22	0.34
5.	0.36	0.57
6.	0.32	0.4
7.	0.26	0.32
8.	0.18	0.3
9.	0.26	0.3
10.	0.36	0.4

These figures, although they have no relation to each other, have a very important bearing in one respect. It may be quite possible that diabetes is originally a disease of the blood and the disease is produced only when the blood proteins are unable to keep the sugar in chemical combination.

So many divergent views and theories have been advanced as regards diabetes that no common causation can be attributed to it; thus for example it is supposed to be caused by derangement of liver function; it has been supposed to be due to disease of the pancreas; some suppose it to be due to disturbance of internal secretion of the adrenals; others attribute it to derangement of the pituitary body whilst the thyroid is also thought to account for the causation of the disease. Hæmorrhage or injury to the medulla has been found to produce diabetes. Phloridzin is also reponsible for producing diabetes experimentally in animals. Long continued dyspepsia has been seen to finally develop into diabetes, particularly in cases of acid dyspepsia. Lastly, loss of the internal secretion of the pancreas has been taken by the modern world as the most important cause of diabetes, the final result of which is the discovery of insulin. Thus we see that there are many different causes attributed to the production of diabetes and hence the difficulty in getting to the root of the matter. Therefore if we find that the blood is the "organ" (if I may be permitted to say so) which is responsible for diabetes then the problem will be nearer solution.

From what we have seen we may conclude that when blood is capable of combining the sugar in such a way that it is powerful enough to hold it in chemical combination, diabetes will then never be produced. But if the blood is powerless to hold the sugar in such combination, owing to any of the causes mentioned above for diabetes, then only does the individual become subject to it. But the severity of the disease depends also on the combining power of the proteins with the sugar. Thus in the table given above those

cases were of severer type in which there was low blood sugar by the pancreatin method than those in which there was more blood sugar by the same method. It means that still more sugar was available for utilisation by the system.

Turning to cases which were treated with insulin, I observed only three such cases up to the end.

Case 1.—Simple diabetes. Course of treatment for three months and every day 20 units of insulin were given. The blood sugar came down to 0.1 per cent. from 0.3 per cent. by the Folin Wu test. When the blood was hydrolysed by $\frac{2}{3}$ NH_4SO_4 the blood sugar was found to be 0.2 per cent and when the same blood was treated with the pancreatin method the blood sugar was found to be 0.3 per cent. This means that the sugar was combined with the protein probably, and was not broken up by the ordinary method during estimation. This case is doing quite well and has not passed sugar in the urine yet, although nearly four months have elapsed since the time of the stoppage of insulin.

Case 2.—Diabetes with tuberculosis of the lungs. In this case, by treatment with insulin and diet regulation for two months the blood sugar was found to be 0.08 per cent. by the Folin Wu method; with the $\frac{2}{3}$ HN_4SO_4 method not much deviation was found; but with the pancreatin method the sugar content was found to be 0.14 per cent. In this case treatment with insulin did not help much in combining the sugar with the proteins and the result was that the patient gradually succumbed and died.

Case 3.—A case of diabetes with a big carbuncle in the back. His blood sugar was originally 0.26 per cent. by the Folin Wu method and with the pancreatin method it was only 0.34 per cent. After treatment with insulin, the blood sugar never dropped below 0.18 per cent. by the Folin Wu method and by the pancreatin method it was never above 0.22 per cent. I predicted it to be a very serious case and it was really so. The patient died 26 days after developing erysipelas. This means that he had lost all balance of the sugar combining power of the blood proteins and hence all energy to recuperate failed and therefore the case ended fatally.

From these observations I may venture to suggest that probably the power of insulin in diminishing the condition of acidosis is due to its sugar combining power, thereby preventing the breaking down of fats which is essentially the cause of the acidosis.

The subject requires careful research. Want of time and opportunity in obtaining cases has been a great drawback to me.

SUMMARY.

1. The blood sugar is higher than what we generally see by the Folin Wu method, when it is done by the pancreatin and Folin Wu method.

2. This excess of sugar is the combined sugar which is not easily breakable.

3. The severity of the disease, diabetes, depends on the amount of the combined sugar; the less the combined sugar, the more severe the case and *vice versa*.

4. Insulin treatment increases the combining power of the blood and thereby diminishes the sugar.

5. It is possible that in this way it prevents the breaking down of fat and thereby prevents acidosis.

A Mirror of Hospital Practice.

A CASE OF THE MENINGOCELE TYPE OF SPINA BIFIDA.

By P. SAVAGE, M.R.C.S., L.R.C.P.,

CAPTAIN, I.M.S.,

Resident Medical Officer, The Lawrence Royal Military School, Sanawar.

KALAVATI, a Hindu female infant, aged one year was brought to me for a fluid swelling in the lower cervical region.

History. The birth was said to have been normal, and the swelling at the back of the neck was noticed at birth. It was then the size of a walnut and had since been gradually enlarging.

On examination, the tumour was three and a half inches long in its vertical axis and sprang from the junction of the cervical and dorsal regions, in the middle line. It presented in appearance the shape and size of a mango with its apex hanging downwards. A few small dark hairs were seen on the skin at the upper attachment. For just less than half its surface the swelling was covered with normal integument. This was continuous with integument over the convexity of the tumour, which was thin and translucent and had numerous small dilated vessels coursing over it.

The accompanying photograph shows well the demarcation between the normal integument and the covering of the meningocele. On handling the tumour, it was obviously felt to contain fluid and on compressing the swelling, the tumour did not diminish in size, nor was there any increase in the pressure at the anterior fontanelle.

Although the infant cried vociferously during the whole examination, no impulse of any sort was perceptible to the hand. The tumour did not pulsate. On transillumination the tumour was uniformly translucent and no

dark patches were seen. The defect in the vertebral canal was made out clearly above and below the pedicle of the tumour.

in order to effect a more rapid cure, excision of the sac was advised.

Operation. Under chloroform anaesthesia, an elliptical incision was made on either side of the tumour, through the healthy skin near its base and an attempt made to dissect out the cystic tumour. Owing to its vascularity and its thickened walls and a desire not to prolong the anaesthesia in the infant, it was decided to terminate the operation as soon as possible. Defining the pedicle, which was a broad band of fibrous tissue (nearly an inch) springing from the gap between the vertebrae and apparently firmly united with the vertebral fascia, the sac was opened very cautiously. It contained no nervous elements and a probe would not enter the vertebral canal. The meningocele was apparently completely shut off. The pedicle was ligated in several places and the redundant tissue was snipped away. A small gauze wick was left in and the wound closed by suturing the adjacent margins of healthy skin.

Progress. On the tenth day after operation, when the stitches were to be removed, the child, who was previously going on quite well, suddenly became paralysed in all four limbs and expired in a few hours from respiratory paralysis due to compression of the cord. (oedematous meninges), in all probability the beginning of an acute septic meningitis.

"The meningocele type of spina bifida is not very common; the meningo-myelocele type is that most frequently seen in living children" (Rose and Carless). Holt (*Diseases of Infancy and Childhood*) gives a very clear description of the meningocele type which is worth quoting. "In this form there is a protrusion of membranes only. The accumulation of fluid is either in the arachnoid cavity or the sub-arachnoid space posterior to the cord. The opening of communication between the tumour and the spinal cord is very small in this variety, usually about one-twelfth to one inch in diameter. There may, however, be no communication. The skin is usually fully developed. The tumour is frequently globular, sometimes pedunculated, and may attain a very large size, being as much as five or six inches in diameter. This is because spontaneous rupture is not likely to occur and the tumour does not become infected except by operative interference. With such tumours patients live to adult life. This variety is most frequently seen in the cervical region. It has the best chance of natural recovery and in its operation gives the best results."

It is presumed that this meningocele, which was quite small at birth, became shut off from the central canal during the growth of the vertebrae and its lining membrane was excited to secrete fluid by persistent irritation, owing to its exposed position on the back of the neck.

The child herself was normal for her age, except that she was rachitic, probably due to her being still a breast fed infant. The head was nineteen inches in circumference and dolichocephalic in shape rather than hydrocephalic. The anterior fontanelle, which did not bulge, was still patent and larger than usual, while the two frontal bones were widely separated in the line of the sagittal suture, so that a deep furrow, easily admitting the tip of the index finger, could be clearly felt between the bones. Except for the gap at the base of the tumour, the remainder of the vertebral canal was normal and the child had no trophic disturbances or paralysis in the limbs.

The conclusion was, that the swelling was a pure meningocele and shut off from the thecal canal. There was no hesitation, therefore, in puncturing the tumour at its lower pole with a five c.c. syringe, and 2½ ounces of a clear fluid, like distilled water, was drawn off. The characteristics of this fluid are given below. The sac was very thick and vascular. Before withdrawing the needle of the syringe about half an ounce of Morton's fluid was injected. The somewhat shrivelled sac was then firmly compressed and pressure maintained with adhesive plaster.

A week later, in spite of the strapping, the tumour had partially filled up with fluid and

The fluid withdrawn from the meningocele was a clear fluid like distilled water; acid in reaction; specific gravity, 1008; albumen, nil; sugar, nil, (Benedict's test). Microscopically it showed no cellular contents.

I am very much indebted to the Rev. G. D. Barne, M.A., C.I.E., for the excellent photograph reproduced.

YAWS IN THE CHIN HILLS.

By D. D. GULATI, I.M.P.,
Sub-Assistant Surgeon, Haka Outpost,
Chin Hills, Burma.

In the issue of the *Indian Medical Gazette* for June 1925, Assistant Surgeon P. Bell, I.M.D., gives an account of yaws as it occurs in the Chin Hills of Burma. May I be allowed to give a brief description of the disease as it occurs in the Haka sub-division of that district? Incidentally I may mention that Dr. Bell is wrong in stating that cases of yaws were treated as being cases of syphilis prior to his arrival in this district; yaws had been known to be prevalent in this district for some years prior to his arrival, and I have myself treated cases of yaws in this sub-division years before Dr. Bell arrived. The disease is more prevalent in this sub-division than in any other in the district, as far as I am aware. I am unfortunately not a pathologist and I have not isolated *Treponema pertenue* from the cases, but the clinical signs and symptoms exhibited by these cases are those of yaws and not of syphilis.

In addition to Dr. Bell's description, I would draw attention to the following clinical points:—

(1) The primary sore may be present upon the angles of the mouth, the anus, or other parts, it has the appearance of a split pea. Fungoid condylomatous growths are common in some cases, especially at the anus. The primary sore may also occur on the finger tips, palms, breasts and at the junction of the scrotum with the penis. The tongue and fauces are not uncommon sites for the primary lesion in suckling infants whose mothers are already infected.

(2) Secondary infections. Of 25 cases treated, 8 were treated in the secondary stage with secondary lesions. After from two to five months from the initial lesion papular and nodular lesions appear scattered irregularly over the limbs and trunk, many of which become chronic. In some cases the primary sore heals completely without any treatment before the secondary lesions come out, but leaving a discoloured scar behind it; in other cases it is still persistent at the secondary stage.

The symptoms are never as severe as those of syphilis. In a few cases the secondary lesions affect the mucous membranes of the mouth and fauces, sometimes even that of the tongue.

The following two cases may be cited as typical:—

Case 1.—Chin male, aged 40. On admission he shewed a condylomatous ulcer of the anus, an indurated ulcer of the scrotum, and chronic scattered lesions—nodules—over the chest, forearms, axillæ and thighs. The duration of the disease had been two years. The primary sore, he stated, had appeared on the right groin and had spontaneously healed without treatment in two months. Three months later a papule appeared at the anus which had given rise to the condylomatous ulcer. He was cured after three injections of novarsenobillon, together with mercury treatment.

Case 2.—A Chin male adult of 40 years, with four children, was admitted for pain in all his joints and bones, of six months' duration. He shewed scattered nodular and papular eruptions all over the body, especially on the arms, axillæ, the palms of the hands and the groins. On the palms some of the lesions had ulcerated. The genitalia were entirely free from lesions. The patient stated that the primary sore had appeared in the axilla and had healed without treatment, leaving a discoloured mark. This patient belongs to Haka village and I have had him under close observation for nearly two years. He was cured by three injections of novarsenobillon and has since shewn no evidence of recurrence of the disease.

Further, his unmarried daughter, aged 18, had an indurated, raised ulcer on the upper lip below the nose. A son, aged 12, had a sore on the prepuce—simulating a soft and not a hard chancre,—a condyloma on the anus, and a warty growth at the angles of the mouth. A second son, aged 6, had lesions on the prepuce, with phimosis, warty growths on the anus and ulceration of the fauces. The mother of these children had ulcers on both breasts, whilst her suckling child, aged two years, had ulcers on its tongue and fauces.

From this description it is fully evident that the disease which we are here dealing with is yaws and not syphilis. Neither father nor mother in this family shewed any lesions upon the genitalia.

In the Haka sub-division the disease appears to run in families. It usually begins in children of some six years or more of age, who act as carriers from house to house; the whole village subsequently becoming infected. The disease is most prevalent in certain tracts, chiefly, Laitet, Wunthu, Keban and Yepai. The Chins are a very dirty race of people, and they tend to disregard infection with yaws.

Their local name for it in the Chin vernacular is "kozeing-mah," which means "celestial sore," and they consider that it is due to the visit of the celestial *nats*, who alone can cure the disease. In general, they are so loth to resort to hospital that many cases are only seen when in the tertiary stage, and some succumb to the disease. I am glad to state, however, that recently the Chins are coming forward voluntarily, and in large numbers, for treatment.

A CASE OF FATAL POISONING BY NITROBENZENE.

By D. R. THOMAS,

CAPTAIN, I.M.S.,

Chemical Examiner, Punjab.

A MAN aged 65 was suffering from habitual constipation and called at a chemist's shop on his way home from work at about 4 p.m. He asked for some almond oil for his complaint. Almond oil, or the oil of sweet almonds, is a common remedy in India for constipation. The old man after obtaining the medicine made his way to a milk vendor, bought a cup of milk, poured some of the medicine into it and drank the mixture. This was at about 5-30 P.M. At about 6 P.M., on arrival at his house, he complained that he was ill and was losing control of his muscles. He could not walk upstairs. He told his son that he had begun to feel ill after drinking the medicine. A doctor was sent for and arrived at 6-15 P.M. and found the patient with a weak and intermittent pulse, rapid respiration, anxious look, and inability to speak. The abdomen was tympanitic and there was incontinence of urine. Spiritus ammoniac aromatici was administered which was vomited. At 6-45 P.M. another doctor arrived who noticed that the vomit was smelling strongly of bitter almonds. In spite of stimulants, strychnine and artificial respiration, the patient gradually became more and more deeply cyanosed and lost consciousness and ultimately died at 3-30 P.M., the following day, 22 hours after taking the oil given to him by the chemist.

A 2-oz. phial found in the patient's pocket was three-quarters full and smelt of bitter almonds. The phial was a plain one and labelled almond oil.

The case was reported to the police as one of suspicious poisoning and a post-mortem examination and a Chemical-Examiner's report was ordered. The post-mortem report was as follows:—

The stomach contained about 10 ozs. of dark-brown fluid smelling strongly of almonds. The mucous membrane was thickened and hardened and there were petechial hemorrhages on the lesser curvature.

The intestine was healthy; the large intestine was loaded with faeces.

Bladder, normal and empty.

Lungs.—Slight congestion with signs of a previous attack of pneumonia which was subsequently verified.

The liver, kidneys, spleen and the brain showed no pathological changes.

The Civil Surgeon forwarded to the Chemical Examiner the following viscera together with a copy of his post-mortem report:—

- (1). A bottle containing the stomach and contents.
- (2). A bottle containing portions of small and large intestines.
- (3). A bottle containing pieces of liver, spleen and kidney.
- (4). A bottle containing a sample of spirit.

The police forwarded to the Chemical Examiner (a) a bottle labelled "almond oil" found on the deceased; and (b) a bottle said to contain almond oil, produced by the chemist who had supplied the medicine originally.

From a study of the case as thus recorded, I suspected prussic acid poisoning, and at once applied the preliminary tests of suspending a drop of silver nitrate solution on a watch-glass over the mouths of the bottles forwarded to me by the police. The results were negative. The contents of the four bottles received from the Civil Surgeon were then examined. The distillates from the first two bottles containing stomach and large intestines (bottles 1 and 2) gave the smell of bitter almonds. But, on proceeding with the chemical tests for cyanides, no reactions were given. This was at first rather puzzling and a possibility of the volatilisation or decomposition of the cyanides owing to the extreme hot weather was considered. The examination of the two bottles sent by the police was then proceeded with further. Both were supposed to contain almond oil. Bottle B., produced by the suspected chemist, proved to contain oil of sweet almonds, but the contents of bottle A., found on the deceased, did not give similar reactions and was evidently not the oil of sweet almonds.

A reference to the text books on toxicology and chemistry, showed that there are four compounds which have a somewhat similar or comparable smell:—

- (1). Oil of sweet almonds.
- (2). Oil of bitter almonds.
- (3). Artificial oil of bitter almonds, (benzaldehyde).
- (4). Imitation oil of bitter almonds or oil of mirbane, (nitrobenzene).

The last two are synthetic products of which (4) the imitation oil of bitter almonds, (nitrobenzene) is poisonous. Nitrobenzene is the mono-nitro-compound of benzene and can be prepared by the action of nitric acid on benzene. It is a pale yellow liquid with a strong smell resembling that of the oil of bitter almonds. It is used in commerce in the manufacture of furniture polish, boot polish and in perfumery. Symptoms of poisoning have occurred from its external use. Internally fifteen drops have proved fatal. Its price is less than half that of good almond oil.

The phial found on the deceased contained a liquid oily substance resembling nitrobenzene and the following tests were applied:—

Test I.—The substance on reduction with zinc and hydrochloric acid produced aniline. The aniline boiled with caustic potash with the addition of a few drops of chloroform gave the characteristic extremely unpleasant smell of phenyl-isocyanide (carbamine).

This test was positive for all the distillates obtained from the viscera, most marked in the distillates from the stomach and intestines and faint in the distillates from the liver, spleen and kidney. The test was negative for the preservative spirit.

Test II.—The substance, on treatment with manganese dioxide and sulphuric acid on the water-bath retained its smell of bitter almonds. The same result was obtained by this test on the distillates from the viscera, i.e., the smell did not disappear.

It was evident therefore that bottle A. found on the deceased contained nitrobenzene, of which presumably about half an ounce had been taken with milk. I reported that nitrobenzene was found in all the organs sent for analysis as well as in the small phial found on the deceased. No poison was found in the sample of spirit.

The almond oil obtained from the suspected chemist's shop (bottle B) proved to be oil of sweet almonds.

On this report the case came up for trial, but was finally dismissed on the following grounds:—

(1). Although a label bearing a certain chemist's name was on the bottle, some of the smaller shops in the bazar possess no labels of their own and so they retain the original label placed on the bottles.

(2). No nitrobenzene was found in the shop of the suspected chemist (search was made some days later).

I have reported this case for two reasons:—

(1). Its toxicological interest. I believe it is the first case reported in the Punjab and possibly in India.

(2). The importance of providing qualified dispensing chemists. At present there is nothing to restrict any one starting a dispensing shop or from selling poisons. The amount of bad dispensing all over India is only too evident, and I would venture to suggest that the cases of accidental poisoning occurring are more numerous than one might care to believe.

It may be noted that the test for aniline was positive only after the nitrobenzene had been reduced by nascent hydrogen. This shows that nitrobenzene is very stable in decomposed viscera.

Nitrobenzene appears to have a direct action on the blood, upsetting its oxygen-carrying capacity. Some toxicologists have described the nitrobenzene haemoglobin spectrum. I was not able to identify the spectrum. This may have been due to the condition of the blood (which was chocolate in colour and decomposed) during the hot weather when the case was examined.

A CASE OF SYPHILIS OF THE LIVER SUGGESTING LIVER ABSCESS.

By VALLABHDAS N. MEHTA, I.M. & S.,
Pirangam.

SUCH cases being by no means uncommon, the following may be of interest to the readers of the journal.

Mr. M., aged about 40, in robust health before his illness, had been suffering from fever with rigors and pain in the hepatic region. This continued for a period of about 2 to 3 months, with occasional remissions of fever and pain. Lately, he began to have paroxysms of shivering with fever and this was followed by profuse sweating. He complained of very severe pain in the whole hepatic region and the whole area below the costal margin was very tender to the touch, so much so that even very light palpation was extremely painful. He was unable to lie on his back or on his left side. Even while trying to sit he had great dyspnoea, and it was with great difficulty that he could be made to sit up even for a few minutes. He was much emaciated and he was very anæmic. Before consulting me, he was treated for malaria and hepatitis for about three months, and he had received about one dozen injections each of quinine bihydrochloride and emetine at different intervals.

Examination of blood films failed to show any evidence of malaria. The leucocyte count which ranged from 7000 to 9000 showed only 16 per cent. mononuclears and 76 per cent. polynuclears.

The upper margin of hepatic dullness was somewhat irregular and as the liver was obviously enlarged it was thought there might be a hepatic abscess.

While closely questioning the patient about his past history and whether he had suffered from any venereal infection, he confessed he had a small sore, which as he said, was immediately cured by three intravenous injections of neo-salvarsan.

Before puncturing the liver for confirming the diagnosis of abscess, I thought it fit to put him on antisyphilitic treatment for a few days, and strange as it may seem, there was very marked and rapid improvement from the third day. In about a week's time the patient felt very much better, and in about a fortnight's time he was well on the way to recovery. Fever and pain entirely disappeared after the third day of treatment.

The possibility of a syphilitic infection of the liver may well be borne in mind while treating such cases, where the symptoms often simulate those of malaria or of amoebic liver abscess.

INTRAVENOUS IODINE IN A CASE OF ABORTION COMPLICATED WITH SEPTICÆMIA.

By B. J. BOUCHÉ, I.M.D.,
Assistant Surgeon, Jullundur.

AN Anglo-Indian lady was admitted to the Station Hospital, Kasauli, on the 24th December 1925.

History of Present Illness.—She was 14 weeks pregnant, and on the 22nd December had developed fever, 101°F., with pain in the uterus and adnexa and a slight "show." On the 23rd the temperature rose to 102.4°F., after which a

Every time the patient got fever his blood was examined microscopically and it was found to contain plenty of malignant tertian rings and a few crescents. Even in the intervals of attacks of fever he was getting quinine sulphate 10 grs. twice a day throughout and occasional doses of calomel. In spite of so much quinine by the mouth he used to get relapses frequently until the administration of intravenous quinine which gave him permanent cure.

I am grateful to Dr. V. J. Lopez, I.M.D., our Medical Officer, for permission to publish the above notes.

RETENTION OF URINE DUE TO AN IMPERFORATE HYMEN.

By M. NASIRUDDIN,

Acting Civil Surgeon, Nanded, Hyderabad, Deccan.

MARIAM BEE, a Mohamedan girl, 18 years of age, a resident of Nanded, was brought by her father to the Civil Hospital complaining of retention of urine on the 17th October 1925 at about 9 a.m.

On enquiry she stated that she had not passed urine for four days, complained of pain in the lower part of the abdomen and back, and fever for a fortnight. She had been in bed since then on account of inability to stand and walk freely. She gave a history of complete amenorrhœa. On admission she was put to bed and examined. She was lean, weak and anæmic. Her breasts were fairly developed. There was a soft fluctuating pyriform swelling about the size of a coconut in the middle of the lower part of the abdomen, extending up to the umbilicus. On auscultation no foetal heart or uterine sounds were heard, so pregnancy was excluded. On examining the external genitalia I found a soft cyst-like tumour about the size of a small orange protruding outside the vulva, the central portion of which presented a bluish-coloured area. The urinary meatus was not visible.

On making a digital examination, I could not find the vagina as the outlet of the par-turient canal was completely blocked by the protruding mass. Thus I was certain that it could not be a prolapse of the bladder or the anterior vaginal wall. I then tried to push the tumour inside to expose the urethral orifice and succeeded in passing a catheter with great difficulty. I drew out about 8 ozs. of urine. Though the abdominal swelling was slightly diminished, yet the soft swelling protruding outside the vulva remained just the same.

After the evacuation of the bladder she was given a warm soap enema, even then the swelling never disappeared. In the evening again a catheter had to be passed to relieve the distended bladder. On further examination no other general disease was detected, except a

rise of temperature to 101.5°F. On enquiry her father admitted that the girl had not menstruated even though she was 18 years of age.

A diagnosis of retained menses was made. The thick bluish-coloured layer in the centre of the prolapsed mass, which entirely obliterated the vaginal canal was a very thick imperforate hymen.

The patient was put on the table and anæsthetised the next day after an enema and catheterisation. I tapped the protruding tumour outside the vulva in the middle line with a trocar and cannula. About 2 pints of chocolate-coloured retained menstrual fluid came out, after which the swelling disappeared gradually. Then the puncture was enlarged with a blunt-pointed bistoury. The uterine and vaginal cavity was douched with warm Condyl's lotion and a drainage tube inserted into the vaginal canal. The patient was sent to bed after dressing.

She was kept on milk diet. The temperature and pulse became normal. Menstruation continued for three more days, after which the tube was removed. She could pass urine freely after this without any further retention.

She was discharged cured on 22nd October 1925.

AN UNUSUAL CASE OF NASAL POLYPUS.

By K. J. SHIVDASANI, I.M.S., B.M.S.,

Medical Officer, Shikarpur.

D.M. a Mohamedan male, aged about 45 years, was admitted for treatment of a tumour in the nose. The tumour was of about three years' duration and had been slowly but steadily increasing in size.

On examination the right side of the nose was considerably distended into an almost globular shape. The external orifice on that side was circular in shape and a little bigger than a silver four-anna piece. The left side was not deformed in shape externally. The right nasal cavity was occupied by a tumour which obliterated the whole cavity and extended into the posterior nares. The septum was pressed into the left cavity, touching the external wall and blocking the passage on that side also. Externally the tumour was flush with the edges of the anterior nares, the four-anna sized surface which was exposed being dry and the rest moist and covered with mucous membrane. The tumour felt hard and fleshy. It extended posteriorly into the pharynx where it was hanging behind the soft palate and uvula like a ball. The last two structures were thinned out and pushed considerably forward. The tumour appeared to grow from the lateral wall of the nose, being non-adherent on other

sides. It was not freely movable inside, being more or less jammed in the cavity.

The patient presented a funny appearance with a large globular nose and open mouth and spoke with a nasal tone; he had considerable difficulty in swallowing and some in breathing which he did through the mouth.

The patient was chloroformed and though he felt suffocated and breathed with difficulty he was got under. The tumour was found attached to the lateral wall for an area about the size of half a rupee. It was freed from its attachment with the knife. At this stage the patient stopped breathing and his pulse also stopped. The pulsation of the aorta, which was clearly visible through the thin abdominal wall, also ceased. An injection of 10 minims of liquor strychnine was given hypodermically, the head of the patient was thrown over the end of the table and artificial respiration started. After an anxious minute or two he started breathing and the aorta throbbed violently. No more chloroform was given, but with two fingers passed behind the soft palate, the tumour was hooked and an attempt made to pull out the polypus via the mouth, as the inner end of the tumour was too big to be pushed forwards through the anterior naris. With the pull the tumour broke into two at its central narrow part or isthmus, and the posterior ball-like half came away through the mouth. An attempt to pull out the rest of the tumour through the anterior nares with gland forceps failed as the tumour was friable. A further attempt to push the tumour forwards with a finger in the posterior naris also failed as the external orifice was too small for the big tumour to pass through.

The side of the nose was therefore slit with a pair of scissors to the extent of an inch and the tumour forcibly pushed forwards with the finger in the posterior naris and delivered intact. There was smart bleeding which was controlled by artery forceps and the cavity was tightly packed with sterile gauze moistened with adrenalin chloride solution. The slit side of the nose was sutured.

All this time the patient remained unconscious though no more chloroform was administered after he had stopped breathing and his head was kept hanging over the end of the table.

The tumour weighed nearly 8 ozs. after treatment. The plugging was removed after two days, when the patient felt very queer with such a roomy nasal cavity. He had regurgitation of fluids through the operated side for a few days, as the posterior naris was too wide to be completely shut off by the soft palate during deglutition. His nasal tone did not disappear immediately, but gradually improved. His recovery otherwise was uneventful. The man was seen again two months later when his nose had taken its

natural shape, the nasal tone had nearly disappeared and he had no trouble of any kind.

Interesting points in the case are the large size of the tumour, its friable nature, its origin from the lateral wall, and the fortitude with which the patient put up with the trouble for such a long time. He sought relief only when the difficulty in swallowing and breathing was becoming severe.

A CASE OF ABNORMAL SALIVARY FISTULA.

By GOPAL SINGH CHAWLA, M.B., B.S.,
Temple Road, Lahore.

A YOUNG Hindu lady of about 23 years of age consulted me for the flow of a limpid fluid from behind the left ear whenever she took food. This complaint had lasted for some 13 years.

On examination I found a tiny fistula, with its orifice about half an inch behind the left ear. On enlarging and deepening the orifice nothing abnormal could be detected, but the wound did not heal under antiseptic dressings.

On asking her to make the same movements with her jaw as if chewing food, no fluid escaped from the fistula; but the moment that food was chewed, fluid commenced to run out of the fistula. The case appears to be clearly one of abnormal salivary fistula; though I regret that I was unable to have the fluid analysed, as its amount was too scanty.

A CASE OF FOREIGN BODY IN THE ABDOMINAL CAVITY.

By K. NARAYANAN, L.M.P.,
Local Fund Hospital, Pultur, S. Kanara.

The patient, an unmarried female, aged 22 years, was admitted to hospital on the 19th January 1926, with abdominal pain and fever of 20 days' duration.

Examination shewed a pyriform swelling, some 3" long and 2" broad, situated between the right anterior superior iliac spine and the umbilicus. It was adherent to the abdominal wall, signs of inflammation were absent over it, but it was indurated and tender on palpation. The uterus could not be palpated easily and there was some rigidity of the right rectus muscle. Vaginal examination shewed nothing except a very foul sero-purulent discharge. The case was diagnosed as one of chronic appendicitis, and prepared for operation the next day.

Operation. An incision was made 3½" in length to the outer side of the right rectus muscle, and on deepening the incision through the subcutaneous fat, hard fibrous tissue was encountered, whilst pus escaped through a small sinus in the tissue. A director was introduced into the abscess cavity, and on introducing the finger and exploring, a hard

iron-like band was felt. On following this to its tip, the end struck upon the finger as if it were a sharp needle.

This suggested a foreign body. The tip of the hard band was seized with pressure forceps, and the foreign body delivered through the wound. It proved to be a wooden stick some 6" in length and 1/10th of an inch in diameter. After its removal pus escaped through the wound, which was next thoroughly well swabbed out, packed with sterile gauze, and allowed to heal by granulation.

The patient made an uneventful recovery, and was discharged cured on the 18th February 1926. She refused to give any history as to how the foreign body came to be there; but it had presumably been inserted *per vaginam* for purposes of procuring abortion.

My thanks are due to Capt. U. Ananthya, M.B., C.M., my medical officer, for permission to publish the notes of this case.

A CASE OF ACCIDENTAL ABDOMINAL INJURY.

By Capt. C. C. DAS GUPTA, M.B.,

Chief Medical Officer, Hossainabad Group of Tea Estates, P. O. Gopal Bagan, Jalpaiguri.

On the 8th April 1924, a coolie boy, aged 10 years, was brought to the Ram Jhora Hospital with a wound about two inches long below the umbilicus, from which some portion of the small intestine was protruding.

While playing, he fell on a piece of broken glass and sustained the above injury.

The boy came to the hospital on foot supporting the coil of intestine in a piece of dirty cloth.

The gut was replaced under chloroform and the wound was stitched, leaving a gauze drain. The parents took the boy away to their hut a few hours later against advice.

The wound healed by first intention and there was no complication.

The case is similar to the one published by Dr. Joglekar in the *Indian Medical Gazette* for November 1925.

A CASE OF DEATH DUE TO BISMUTH INJECTION.

By C. F. CHENOY, M.B., B.S., D.P.H. (Lond.)

District Civil Surgeon and Sanitary Officer, Raichur.

THE following case ending in death within two hours after injection of bismuth is worthy of record.

One night at 8-45 P.M., I was called in to see a Hindu patient. The history given was

that the patient was given an intramuscular injection into the buttock by a doctor at 7 P.M. The condition of the patient reported was that he was unconscious. On further enquiry I was told that after receiving the injection the patient began complaining of thoracic pain and cramps in both legs. He began to have palpitation. This was followed by perspiration and suffocation. The medical attendant was called. The doctor came over and could not make out the trouble and left the patient, advising the relations to send for the Civil Surgeon. On hearing this, the patient tried to get up, but could not do so as he was paralysed.

On examination the patient was unconscious. Dyspnoea was markedly present, the pulse was weak and rapid, as also the respiration. The face was pale, pupils contracted, and perspiration abundant. The heart sounds were weak. Coarse râles were heard in the chest but the percussion gave a clear note. Both his legs were paralysed. In this condition death took place in my presence within an interval of ten minutes after my arrival and within two hours after the injection. The injection tube which was shown was one of "Neo-Trepol".

The cause of death was due to the injection of "bismuth" being inadvertently given into the vein of the gluteal region. Bismuth is ten times as toxic when injected intravenously as when given subcutaneously and the preparation injected being insoluble the mechanical effect from blocking of the veins was well marked.

AN UNUSUAL CASE OF PNEUMONIA IN AN INFANT.

By Capt. C. C. DAS GUPTA, M.B.,

Chief Medical Officer, Hossainabad Group of Tea Estates, P. O., Gopal Bagan, Jalpaiguri.

ON the 31st December 1925, I was called to a case of lobar pneumonia in a child 3 months old. The baby had been suffering from slight cough for four days, but as there was no rise of temperature the parents took no notice.

On examination, the base of the left lung was found to be consolidated. The patient was dyspnoeic and extremely cyanosed. The temperature was 97°F. Next morning the base of the right lung was found affected and he expired at noon.

The special feature of the case lies in the fact that the temperature never rose above 98°F. The explanation seems to be that the thermogenic centre was so overwhelmed by the toxins that there was no reactionary fever.

MAY.

TUBERCULOSIS.

COMPARATIVELY little work has been done on tuberculosis in India in spite of the fact that the disease is one of the great causes of death in this country. We might excuse the neglect of the study of tuberculosis by suggesting that the malady is cosmopolitan and therefore we need only keep in touch with the research work which is being carried out in other countries. This, unfortunately, is an assumption which is quite unjustifiable, for the reason that tuberculosis in India is by no means the same as tuberculosis in Europe, and it is necessary for us to face the undoubted fact that tuberculosis as it occurs in India and the tropics generally must be regarded as one of our tropical diseases. It is likely, for example, that bovine tuberculosis is an uncommon disease in India, it is likely that comparatively few children in India become immunized against the disease by suffering from the mild attacks of gland tuberculosis which are so common in Europe.

It is a matter of common knowledge that tuberculosis of the lung in India usually runs a much more rapid course than the disease in Europe, and although this may to some extent be due to the lower resisting powers of the people of this country, it is also likely that the absence of the immunity which results from mild forms of the disease in childhood plays an important part.

If India enjoys the advantage of escaping from bovine infection through milk, she also suffers from a corresponding drawback for the reason that bovine infections in childhood probably serve to confer a valuable degree of immunity against infection from human sources.

If we bear in mind the probability that our tuberculosis problem is by no means identical with that of European countries, we can derive much useful knowledge of the disease by studying the work which is being done in Europe.

A valuable contribution to the subject has been made by writers in the *Tuberculosis Number of the Edinburgh Medical Journal*, (March 1926). Drs. W. D. Munro and W. M. Cumming write an instructive article on the virulence of tuberculous viruses. Starting from the observed fact that small doses of bovine tubercle bacilli are deadly to the ox and rabbit, while similar doses of human bacilli are of low virulence to these animals, they have examined a large number of strains of bacilli from human cases of tuberculosis. They find that in pulmonary tuberculosis

nearly all the strains are of the human type at all ages, in the cervical gland infection of adults nearly all are also human, while the cervical gland tuberculosis of young children is more frequently due to bovine bacilli.

Bone and joint tuberculosis is nearly always due to the human type of bacillus, while abdominal tuberculosis in young children is rather more frequently of bovine origin (13 to 9), although in adults it is usually caused by the human type (14 to 4). They suggest that the bovine strain may possibly become modified in the human body so that it gradually assumes the characters of the human strain, and in support of this view they point to the existence of a few strains which are intermediate in character between the bovine and the human. Sir Robert Philip and Dr. J. C. Simpson deal with the production of "certified milk" and show to what a degree of perfection methods of dairy farming have attained in some places.

The cattle are tubercle free as shown by the tuberculin test, they are housed in well lighted and well ventilated sheds which are kept scrupulously clean. The cows are carefully groomed; before milking, the hands of the milkers are cleansed as for a surgical operation; the udders of the cows are carefully washed, the dairy utensils, overalls of the milkers, etc., are sterilized by steam. The first milk is rejected, a special pail is used with a lateral opening which prevents dirt or hair from falling into the milk. The milk is cooled to 50°F. and bottled in sterilized bottles which are sealed and capped, the milk is not touched by hand at any time. The milk which is obtained in this way contains less than 1,200 bacteria per c.c. after 24 hours, and all the bacteria are of the lactic group; these being normally present in the cow's udder. Dr. L. Findlay contributes an article on the incidence of tuberculosis in childhood, from which it appears that all forms of medical tuberculosis are far more common in the first three years of life than in later years, the curve falling rapidly till about the 10th year.

He points out that tuberculosis of the lungs in childhood is an acute or subacute disease which is almost always rapidly fatal, evidence of healed pulmonary tuberculosis in young children is very rarely found in the post-mortem room.

He also shows that pulmonary tuberculosis in young children is nearly always a diffuse disease of which the only physical signs may be wheezing râles with slight diminution of resonance all over the lungs.

The x-ray picture is that of widely diffused discrete shadows which usually show the "snow-storm" appearance. Localized shadows either at the apex or base rarely indicate tuberculosis, and the so-called hilum shadows can usually be disregarded.

Acute miliary tuberculosis cannot be diagnosed by an x-ray picture. He often obtains sputum from young children by swabbing the throat with a finger covered with gauze, in this way coughing is induced and the sputum can be collected with the gauze for examination.

The Von-Pirquet test was found to be of very little value as so many children give a positive result from old healed tuberculosis of the glands.

It is to be hoped that a systematic study of tuberculosis in India will be taken up, preferably in the first instance at all events by men who have an intimate knowledge of research work in tuberculosis in European countries. We must confess that our knowledge of the disease in India is based for the most part on general clinical observations, and even these have not been made under such conditions as to permit of accurate analysis. What we do know, only too well, is that tuberculosis in India is a very widespread disease which under existing conditions is exceedingly difficult to control. We have also good reason to believe that the prevalence of the disease is closely associated with low nutrition, with slums, and with grossly unhygienic habits of life. Special research into the disease will not merely be of great value in giving us more accurate knowledge of the disease, it will attract attention to the necessity for tackling the problem of prevention.

Most of the efforts of medical men in India are expended on the hopeless task of trying to cure the victims of the disease. What is needed is to attack the enemy in his stronghold, rather than to carry on a feeble guerilla warfare against his widespread roving bands, which in most cases have already gained victory before we are aware of their presence.

Current Topics.

All-India Conference of Medical Research Workers.

THE following is an abstract from the proceedings of this conference which was held at the Calcutta School of Tropical Medicine in December, 1925:—

First day (15th December, 1925).

Thirty-eight delegates from the various provinces and from the Army attended.

The Conference was opened by Major-General Sir R. C. MacWatt, Director-General, Indian Medical Service, who presided and delivered a short address on the present position of the Indian Research Fund Association and on the opportunity afforded by the partial restoration of the grant-in-aid for the undertaking of new and important researches. He also announced the fact that a tablet had been placed in the Central Research Laboratory, Kasauli, to the memory of the late Major Cragg, I.M.S.

The Conference proceeded to discuss the publication of the *Indian Journal of Medical Research*. Lieutenant-Colonel Graham explained the accounts of the *Journal* and the method of conducting the *Journal*.

Lieutenant-Colonel Christophers, the present Editor of the *Journal*, made a few remarks on the subject of

publication; the published matter was now very much increased and the memoirs that had been published during the year were of a very useful nature, some being in wide request. It was therefore a good way of broadcasting. The interleaving of the *Journal* with advertisements has been a financial success, but he himself would prefer to see these advertisements at the beginning and the end of the *Journal*. The discussion on this point became general. The policy of the Editorial and Secretarial staff was unanimously endorsed.

A statement which had been circulated showing the financial position of the Indian Research Fund Association during the years 1925-26 and 1926-27 was read and certain points in this statement were explained by the Secretary. The cash balance was much greater than was anticipated, partly on account of the original estimate of the Accountant-General being a provisional one and also because, in some cases, the total grant for certain researches had not been expended and the balance had been returned to the Fund. Contributions of the local Governments to the Kala-azar Commission had not been received in the cases of Bengal and Madras; but it seemed possible that in the former instance there had been an error and the grant would be renewed this year. The pay and allowances of eight officers holding unspecified appointments under the Indian Research Fund Association, which had hitherto been shown under 32—Medical [Budget, D. G., I.M.S.] was, by order of the Government of India, to be shown in future under 33—Public Health; hence provision for pay, leave pay, and pension contributions for these eight appointments was now included in this budget.

The research programme in operation during the year 1925-26 was then read. This programme included the researches taken up during the year as a result of the restoration of the Rs. 3 lakhs grant-in-aid.

The President then invited the research workers present to make a few remarks on their work as at present being undertaken. A brief resumé of these is appended under sub-heads (I) to (XLII).

(i) *Cinchona Alkaloids Inquiry*.—Major Acton made a few remarks on the nature of this inquiry; the main line of work had been experimental pharmacological investigation of the effect of the combination of alkalies and quinine and an investigation into the diffusibility of the various alkaloids.

(ii) *Quinine and Malaria Inquiry*.—Major Sinton gave a resumé of his work, a fuller report of which appeared in the January 1926 issue of the *Indian Journal of Medical Research*. He said that the quinine-plus-alkali treatment produced 90 per cent. of cures. One of the main difficulties was seeing that the patient actually got the quinine.

(iii) *Anti-plague Vaccine Inquiry*.—In the absence of Dr. Naidu, who was carrying out this investigation, Major Morison explained the lines on which the inquiry was being carried out; the method of preparation of plague vaccine had not been changed for 25 years, and, in view of the great advance during the last few years in vaccine therapy, it was thought that some improvement in the vaccine could be effected.

(iv) *Helminthic Inquiry*.—Dr. Korke explained that his work had been mainly a geographical survey of certain parasites.

(v) *Kala-azar Treatment Inquiry*.—Dr. Brahmachari explained that his investigation had been mainly directed to finding a more powerful antimony compound for the treatment of kala-azar and also one that could be used intramuscularly and orally.

(vi) *Kala-azar Commission*.—Lieutenant-Colonel Christophers said that at last year's Conference he had remarked that there were strong reasons for supposing that infection occurred by means of contamination as in the case of typhoid fever, and that the work of the Commission had been planned to investigate the possibility of infection occurring in this manner. The work at the Calcutta School of Tropical Medicine had shown that, not only were there strong epidemiological

reasons for suspecting the sandfly—*Phlebotomus argentipes*—but that the causative parasite actually developed with great rapidity in the gut of this fly. The Commission had felt justified in largely abandoning their original line of work which had given entirely negative results, and in following the lines suggested by the findings of the workers in Calcutta. The Commission had been able to confirm these findings and recently to carry the matter a step further and show that there was a heavy infection of the pharynx in certain infected sandflies.

Major Shortt, who had become the Director of the Commission since Lieutenant-Colonel Christophers had left it, said that by cutting sections of the sandflies he had been able to show massive infection of the buccal cavity on the 8th day after the infecting feed and, in a few flies, on the 5th day.

Lieutenant-Colonel Christophers described the mouth parts of the sandfly and said that in his opinion it was almost impossible for the flagellates not to infect the wound when a sandfly with an infected buccal cavity fed on a man.

(vii) *Kala-azar Inquiry at the Calcutta School of Tropical Medicine.*—Dr. Napier made a few remarks on the events which had led to their experiments with the sandfly—*Phlebotomus argentipes*—and explained that the work during the year had been mainly field work directed towards studying the bionomics of the fly in nature and under artificial conditions. Up to the end of August, 8,784 flies had been bred and the feeding experiments had been repeated at different times throughout the year; controls had been done with another sandfly, *Phlebotomus papatasi*; all the controls had been entirely negative. Dr. Smith added a few remarks about the Calcutta inquiry.

(viii) *Leprosy Inquiry by Dr. Muir.*—Dr. Muir said that he had been investigating the Wassermann reaction in leprosy with the help of Major Lloyd; they had come to the conclusion that the positive reaction was due to syphilis, and they had been able to show that when patients were treated for this condition their leprotic lesions improved very markedly. Investigations had shown that the hydnocarpus oil, when prepared from fresh seeds, was actually less painful for injection than the esters. It was much cheaper than the esters.

(ix) *Bovine Tuberculosis Inquiry.*—Dr. Soparkar explained that, though tuberculosis amongst cattle was supposed to be rare in India, his experience had been that it was fairly common; he had found between 2 and 3 per cent. infected in all the places that he had investigated. He said it was true that local lesions were the rule in this country; he had only rarely encountered lung lesions which in England occurred in 50 per cent. of infected cattle. He said that he was testing the resistance of various breeds of cattle and that contrary to expectations he had found cattle of mixed strains (partly English) more resistant to infection.

(x) *Sprue and Bilharziasis Inquiry at the Haffkine Institute, Bombay.*—Major Morison said that Dr. Hamilton Fairley had submitted a report of his work for publication in the *Indian Journal of Medical Research*. Lieutenant-Colonel Mackie was investigating the relationship between sprue and Monilia. Investigation into the bacteriology and chemistry of the stools in sprue was being undertaken; the main result so far was that a streptococcus had again fallen under suspicion.

(xi) *Indian Indigenous Drugs Inquiry.*—Major Chopra explained that two sets of investigations were being undertaken, the first was the investigation of the indigenous variety of drugs of known value in order to find out if their pharmacological standards were as good as those of the imported drugs. They had been able to show that digitalis grown in Darjeeling and santalin from Kashmir were as good as the imported varieties of the drugs. The second line of work was the investigation of the value of certain drugs used in the indigenous systems of medicine; some of these have

been found to have decidedly beneficial action in certain disease conditions.

(xii) *Lathyrism Inquiry by Major Anderson, I.M.S.*—Lieutenant-Colonel Christophers explained that, as Major Anderson was shortly proceeding on leave, the inquiry on the lines proposed would have to be closed down as nobody suitable was available to carry on the work; some results had already been published in the *Indian Journal of Medical Research* and others would follow.

(xiii) *The Indian Culicid Inquiry by Captain Barraud.*—Lieutenant-Colonel Christophers explained that Captain Barraud was continuing to direct this inquiry while he was working with the Kala-azar Commission in Assam; it was hoped that before very long he would be in a position to devote more of his time to the completion of this important inquiry.

(xiv) *The Antivenene Inquiry by Father Caius.*—Major Morison explained that various circumstances had prevented this work being undertaken and that the sum in question had not been drawn.

(xv) *Malaria Inquiry at Lahore by Major Hughes, I.M.S.*—Lieutenant-Colonel Graham explained that Major Hughes was carrying out a laboratory inquiry into the biochemical changes in the blood in malaria with special reference to quinine administration.

(xvi to xxv) *Military Inquiries:*—
Malaria Survey at Allahabad by Captain M. L. Dhavan, I.M.S.

Malaria Inquiry at Kohat by Captain A. C. Chatterji, I.M.S.

Ankylostomiasis Inquiry at Dehra Dun by Captain G. Covell, I.M.S.

Peshawar Sandfly Inquiry by Lieutenant-Colonel McCombie Young, I.M.S.

Heat Exhaustion and Heat Stroke Inquiry by Colonel F. H. G. Hutchinson, C.I.E., I.M.S.

Anæmia Inquiry at Bombay by Captain Basu, I.M.S.

Pyrexia Inquiry at Quetta by Director of Pathology, Baluchistan District.

Researches at the Poona District Laboratory by Major Manifold, R.A.M.C.

Researches at the Wellington District Laboratory by Major Dunbar, R.A.M.C.

Researches at the Calcutta District Laboratory by Captain Mearns, R.A.M.C.

On behalf of the Director of Medical Services in India, Lieutenant-Colonel Mackenzie thanked the President for sending an invitation to the Military Medical Services to attend this Conference and to take part in the research work. He explained that they had now got a trained pathologist at each of the district laboratories and that they had been able to undertake the ten above mentioned inquiries. The main insect-borne diseases with which the Army had to contend were malaria, sandfly fever and dengue; the sandfly inquiry had been completed, as also had an ankylostomiasis inquiry; Captain Chatterji at Kohat was testing various mosquito repelling substances; most of the other inquiries had only just commenced and he had little detailed information as to their progress.

(xxvi) *Malaria Classes at the Central Research Institute, Kasauli.*—These classes had had to be discontinued until this year. Major Sinton detailed the course given in May, 1925; lectures were given at Kasauli and the field work was carried out in the Terai near Ambala.

(xxvii) *The Preparation of a Malarial Bibliography.*—Major Sinton, who has been entrusted with this work, said that there was an impression in Europe and America that little work had been done in this country on malaria; the real truth was that much had been done, but that little notice was taken of each individual piece of work and some most valuable reports were buried in the provincial Secretariats; the quickest and surest way to get access to these reports was to visit each Secretariat in turn and dig out the information. The Government of India had made special arrangements

for his tour of inquiry which had begun and would last three months.

(xxviii) *Plague Inquiry in the United Provinces under the supervision of the Director of Public Health.*—Lieutenant-Colonel Dunn explained that this was only the nucleus of a much larger inquiry which he hoped to undertake next year; he gave a few examples of the results of the inquiry. He had found that the percentage of the different species of flea varied markedly from month to month, from village to village and even within a village; a very large staff of medical officers of health were employed in various parts of the province testing the late Major Cragg's theory that *astia* does not play an important part in spreading the disease; as a whole the figures supported this suggestion but in certain areas they appeared to contradict it. The work was proceeding.

(xxix) *Plague Inquiry at the Haffkine Institute, Bombay.*—Major Morison explained that various forms of medicinal treatment for the disease were being tested on infected rats; infection experiments on rats were also being carried out and it had been observed that, at certain times of the year, infection would not take place.

(xxx) *Cholera Statistical Inquiry by the Director of Public Health, Madras.*—Major Russell said that the Madras figures had given some very interesting results, so that inquiry had been extended to embrace the figures of other provinces.

(xxxi) *Cholera Inquiry in Bengal by the Director of Public Health.*—Lieutenant-Colonel Fry explained on behalf of Major Stewart that investigations had been started in two centres, one at Khulna and the other at Mymensingh; in the former, five infected villages had been examined and in only one of these was there definite evidence of spread by migration; serological and bacteriological examination of the blood and stools of the contacts was undertaken. In the latter area no infected villages were found, but a village which had an epidemic last year was examined. The work was proceeding.

(xxxii) *Researches on Cholera Treatment by the Director of Public Health, Madras.*—Major Russell stated that this work had only just commenced; a large number of doses of ordinary cholera vaccine had been given and about 2,000 doses of Professor Besredka's bilivaccine had been obtained and distributed in certain villages where careful watch could be kept on the results and as effective a control as possible arranged for.

(xxxiii) *Schistosomiasis Inquiry by the Director of Public Health, Burma.*

(xxxiv) *Beri-beri Inquiry by the Director of Public Health, Burma.*—Major Taylor said that eight cases of schistosomiasis had been reported but since then no further cases had been observed so that little investigation could be carried out. With reference to the beri-beri inquiry it had been observed that small outbreaks occurred in isolated places such as schools and police outposts; the outbreaks usually occurred at the end of the monsoon and the rice was usually found to be in a bad condition and badly stored.

(xxxv) *Field Ankylostomiasis Inquiry by Dr. Chandler.*—Lieutenant-Colonel Megaw explained that this inquiry had only just been commenced and that Dr. Chandler who would be present on the following day would give details of the line of research.

(xxxvi) *Deficiency Diseases Inquiry by Lieutenant-Colonel McCarrison, I.M.S.*—Lieutenant-Colonel McCarrison said that he considered that the absence of vitamin B. was a very important factor in the production of epidemic diseases and that it was a factor which was overlooked by most workers; he said that he had now been able to produce real beri-beri in pigeons and that this was a very different disease from polyneuritis gallinarum. He was carrying out experiments with different varieties of grain and was also testing the effect of different manures on various varieties of grain.

Second day (16th December, 1925).

The Conference met at 10-30 A.M.; the discussion on the research programme at present in operation was continued.

(xxxvii) *Maternal Mortality and Morbidity in Child-birth in India.*—Lieutenant-Colonel Graham explained the nature of this inquiry, emphasised its importance, and stated that Dr. Margaret Balfour had come to India at her own expense to work on this subject; the sum granted was to cover expenses connected with the inquiry. Dr. Balfour will have at her disposal a pathologist supplied through the kindness of Dr. Scott from the Women's Medical Service.

(xxxviii) *Lathyrism Inquiry by Dr. Simonsen in England.*—Lieutenant-Colonel Graham explained that this sum had been granted for expenses in connection with the lathyrism inquiry; Dr. Simonsen while on leave wished to take advantage of the special laboratory facilities at his disposal in England in order to work out certain chemical details.

(xxxix) *The Bio-chemical Section at the Haffkine Institute, Bombay.*—Major Morison said that the bio-chemical section had been working on sprue until August this year but, since Major Sokhey had taken charge, work had been done on vaccine therapy.

(xl) *Cholera Inquiry in the Asansol Mining Settlement.*—Dr. Tomb, Chief Sanitary Officer, Asansol Mines Board Area, who is directing this inquiry, described the lines on which the inquiry was to be carried out; he was being assisted by Captain Maitra, I.M.S., who was carrying out the bacteriological work of the inquiry.

(xli) *Relapsing Fever Inquiry.*—Lieutenant-Colonel Cunningham explained that this inquiry had been going on for some time prior to his furlough, at the King Institute, Guindy, and had been financed by the funds of this Institute; but he was now appealing for a grant-in-aid to continue this work at Kasauli. One of the points that this inquiry had so far brought to light was that, serologically, the organism that produced the first attack differed entirely from that causing the relapses; if one called the primary organism A then the organism that appeared to cause the relapse was B, but if the primary organism had the serological characteristics of B, then the organism causing the relapse would be A. This phenomenon required further investigation.

(xlii) *Inquiry on Dog Piroplasmiasis in Madras.*—Lieutenant-Colonel Graham spoke regarding this inquiry in Major-General Symons' absence.

The Conference then proceeded to consider the research programme for 1926-27 on the basis of the present income of the Association. The President invited the members to state the lines on which they proposed to carry out their several researches during the next year.

(1) *Malaria.*—(i) *Quinine and Malaria Inquiry by Major Sinton.*—Major Sinton said that this inquiry had been going on during the last few years but that as he was hoping to go on leave shortly it was for consideration whether the inquiry should be continued. The Director of Medical Services in India had very kindly deputed Captain Bird, R.A.M.C., to take charge of the Convalescent Malarial Depot and to act as his assistant in this side of the inquiry with a view to his carrying on the work when he, Major Sinton, went on leave. It was an important inquiry and should be continued. Lieutenant-Colonel Graham said that the work of Majors Acton and Sinton on quinine and other cinchona alkaloids had been quoted at a recent Cinchona Conference and had helped to influence the decisions of this Conference. He also pointed out that the League of Nations had started an inquiry into the world production of quinine and other cinchona alkaloids and would soon be anxious to quote our work so that the subject should be considered an important one. Major Acton said that there were many important points to be investigated yet, such as the least possible dose of

quinine or other alkaloid that would produce a given percentage of cures. Lieutenant-Colonel Graham proposed and Major Acton seconded a proposal that this inquiry should be continued; the Conference unanimously supported the proposal.

(ii) *Malaria Inquiry by Major Hughes at Lahore.*—Lieutenant-Colonel Graham explained this in detail and Major Sinton said that this inquiry was being carried on in close association with his work and considered that it should be continued; the Conference agreed.

(2) *Plague.*—(i) *Anti-plague Vaccine Inquiry at the Haffkine Institute, Bombay.*—Major Morison suggested that this inquiry should be continued; the Conference agreed.

(ii) *Plague Inquiry in the United Provinces under the Director of Public Health.*—Lieutenant-Colonel Dunn said that this inquiry would continue during the next year; the United Provinces Government had made a grant; but, by an error, no proposals had been sent to the Indian Research Fund Association; he said that the grant-in-aid given last year had not been fully expended as it was for a period of one year but he was afraid that the work would be hampered if no further grant were made next year.

The President said that he concluded that the demand had the sympathy of the Conference but that Lieutenant-Colonel Dunn's new demand would have to be considered by the Scientific Advisory Board, when he put up his proposals. The Conference agreed.

(3) *Cholera.*—(i) *Cholera and Small-pox Statistical Inquiry by Major Russell.*—Major Russell suggested that this inquiry should be continued during the next year; the Conference agreed.

(ii) *Geographical Surveys of Cholera, Plague and Relapsing Fever and Researches on Cholera Vaccine Therapy and Cholera Treatment by Major Russell, I.M.S., Director of Public Health, Madras.*—Major Russell explaining this demand said that the largest item was for the purchase of bilivaccine. Major Taylor said that as the value of this vaccine was by no means proven and as, even if it were given on a large scale, there would be considerable difficulty in estimating the results, he considered that the sum proposed to be expended was rather a large one. Captain Maitra said he had tried the oral vaccines in animals and found that agglutinins appeared in their blood; he considered that an experiment of this nature on man was important. Lieutenant-Colonel Graham pointed out that the vaccine had been tried in Europe and was looked upon favourably, that the eyes of the Office International d'Hygiene Publique and of the Health Committee of the League of Nations were focussed on India's attitude in regard to cholera prevention and that there did not seem to be any excuse for holding back a trial of it in India. A general discussion followed. The President pointed out that last year this same Conference suggested the importance of accurate disease surveys and that if they did not support the demand made by Major Russell's inquiry they would be going back on their last year's resolution. The question was put to the vote and the meeting unanimously supported the demand.

(iii) *Cholera Inquiry in Bengal by the Director of Public Health.*—Lieutenant-Colonel Fry said that Bengal was universally accepted as the home of cholera; an interesting point was to know how the disease was carried over from season to season. The work that was being undertaken was directed mainly at solving this problem. The Conference agreed to the continuing of this investigation.

(iv) *Cholera Inquiry in the Asansol Mining Settlement by Dr. Tomb.*—Dr. Tomb said that the work would be carried out on the lines on which they had already begun. The Conference agreed to this grant.

(4) *Helminthology.*—(i) *Helminthology Inquiry by Dr. Korke.*—Lieutenant-Colonel Graham explained that there were two proposals, one that the work should be continued on the lines which had been approved last year, in which case the demand was for Rs. 17,535, and the second was for a further scheme which would

mean an addition of Rs. 4,465. Dr. Korke said that the subjects of entomology and veterinary science were so intermixed with this subject that it was advisable for him to have a veterinary and an entomological assistant; the extra demand was for the pay of these two assistants. A discussion followed. The opinion of the Conference was taken and it was decided that the grant for the inquiry on the lines on which it was carried out last year should be made, but that the question of increased grant should be referred to the Scientific Advisory Board.

(ii) *Field Ankylostomiasis Inquiry by Dr. Chandler.*—Dr. Chandler asked that this inquiry might be continued during the ensuing year; the conference agreed.

(iii) *Helminthic Survey at Dehra Dun.*—It was agreed that this research should be continued.

(5) *Kala-azar.*—(i) *Kala-azar Treatment Inquiry by Dr. Brahmachari.*—Dr. Brahmachari explained that the work would be carried on on the same lines as heretofore. The Conference approved of the continuation of the inquiry but suggested that certain details with regard to the pay of the staff should be referred to the Scientific Advisory Board for decision.

(ii) *Kala-azar Commission.*—The continuance of this was approved.

(iii) *Kala-azar Inquiry at the Calcutta School of Tropical Medicine.*—Major Knowles considered that it was important that this inquiry should be continued as the problem of how kala-azar was transmitted was not yet fully solved, and, even when this was solved, there was much work to be done on the subject of prevention. The Conference agreed.

(6) *Leprosy Inquiries by Dr. Muir and Dr. Nishi Kanta De.*—It was agreed that these inquiries should be continued.

(7) *Bovine Tuberculosis Inquiry by Dr. Soparkar.*—Dr. Soparkar suggested that this inquiry should be continued on the lines on which it was at present being carried on. Lieutenant-Colonel Graham gave a resumé of the position as discussed between the Government of India Agricultural Adviser, the First Bacteriologist at Muktesar and himself and pointed out that, heretofore, animals for the experiments had been supplied by the agricultural department but that in future there might be difficulty about animals. He suggested that the whole matter be referred to the Scientific Advisory Board; the Conference agreed.

(8) *Spruce Inquiry at the Haffkine Institute, Bombay.*—The Conference agreed to the continuance of this inquiry.

(9) *Indian Indigenous Drugs Inquiry.*—Major Chopra said that the work would be continued on the same lines as heretofore; the Conference agreed that the inquiry should continue.

(10) *Beri-beri Inquiry by the Director of Public Health, Burma.*—It was agreed that this inquiry should continue.

(11) *Deficiency Diseases Inquiry by Lieutenant-Colonel McCarrison, I.M.S.*—Lieutenant-Colonel McCarrison considered that malnutrition through improper diet was one of the principal causes of disease in India and that the subject on which he was working was one of the greatest importance; he proposed to continue on the lines on which he had been working this year; the Conference agreed to the continuance of this inquiry.

(12) *Maternal Mortality and Morbidity Inquiry at Bombay.*—Lieutenant-Colonel Graham read a letter from Dr. Balfour outlining her programme of research; the Conference approved of the continuance of this inquiry.

(13) The six inquiries being carried out by officers in military employment were then discussed. Lieutenant-Colonel Mackenzie outlined the various programmes, and Lieutenant-Colonel Graham supplemented by further details. The following inquiries were approved by the Conference:—

(i) Heat Stroke Inquiry at Allahabad.

(ii) Researches at the Poona District Laboratory by Major Manifold.

(iii) Researches at the Wellington District Laboratory by Major Dunbar.

(iv) Researches at the Calcutta District Laboratory by Captain Mearns.

(v) Complement Fixation Test for Malaria by Major Little at Mhow.

It was suggested that the following inquiry should be referred to the Scientific Advisory Board for further consideration:—

(vi) Anæmia Inquiry at Colaba by Captain Basu, I.M.S.

(14) *Lathyrism Inquiry by Major Anderson, I.M.S.*—Lieutenant-Colonel Graham said that Major Anderson would presently proceed on leave; there was a proposal to extend the scope of this inquiry and if this were done it would probably be essential and advisable to employ a whole-time worker. There were various points to be considered and he thought that it was a matter that might be left to the Scientific Advisory Board; the Conference agreed to this.

(15) *Indian Culicidæ Inquiry by Captain Barraud.*—Lieutenant-Colonel Graham read a letter from Captain Barraud and explained that he was continuing the inquiry in his spare time and during the "off" sandfly season in Assam. The continuance of this inquiry was agreed to.

(16) *One-half the recurring charges of the Bio-chemical section at the Haffkine Institute, Bombay.*—This expenditure which had already been agreed to by the Governing Body was approved by the Conference.

(17) *Cost of two Professors at the Calcutta School of Tropical Medicine.*—Lieutenant-Colonel Megaw explained that, although these were nominally teaching appointments, the Professors had time for research work and the amount of work turned out by each of them in his opinion alone justified the expenditure; if this sum had not been granted originally by the Scientific Advisory Board the School would most probably never have come into existence, and that its existence was still to a large extent dependent on the continuation of this grant. He also pointed out the very important work performed by the School in teaching young research workers. The continuance of the grant was unanimously approved.

The three items in connection with administration, the *Indian Journal of Medical Research* and the Library at Kasauli were passed by the Conference without discussion.

(18) *Relapsing Fever Inquiry by Lieutenant-Colonel Cunningham.*—Lieutenant-Colonel Cunningham had already explained the lines on which the inquiry was being carried out; the Conference agreed to its continuance.

(B) Proposals for new inquiries to be undertaken during 1926-27 were then discussed.

(19) *Skin Diseases Inquiry by Major Acton at Calcutta.*—Major Acton said that the subject of skin diseases was very much neglected in this country and that as he had now worked up a large out-patient department he felt that there was a good opportunity for doing some research work on this subject; many skin diseases appeared to be due to intestinal intoxication; this was one of the points which he proposed to investigate. The Conference approved of this inquiry.

(20) Lieutenant-Colonel Graham suggested that consideration of the other five new military inquiries which had been proposed might be left to the Scientific Advisory Board as full details of these inquiries were not available and more information regarding them was essential. This was agreed to.

(21) Lieutenant-Colonel Graham explained that two other proposals had been received too late for inclusion in the schedule; the first was an inquiry by Major Wright into the bacteriology of endocular inflammation and the second was on cancer by Dr. Chatterjee. Major Acton reminded the Conference that a short time ago Major Wright had been a valuable bacteriological worker and strongly supported the request of this grant; Lieutenant-Colonel Cunningham seconded this proposal

and the Conference agreed that it should have the sympathetic consideration of the Scientific Advisory Board. *Re* the other proposal from Dr. Chatterjee to carry out research on cancer, Lieutenant-Colonel Graham said that he thought that it was a matter for the Scientific Advisory Board to settle. The suggestion was agreed to.

Third day (17th December, 1925).

The Conference having met at 10 A.M., the President opened the proceedings by reading the following note prepared by the Secretary, on the proposal for a permanent Central Malaria Organisation:

"The note which has been prepared by the Director, Central Research Institute, Kasauli, in consultation with the Director-General, Indian Medical Service, and the Public Health Commissioner with the Government of India, embodies proposals for the creation of a permanent malarial section at the Central Research Institute, Kasauli. We are agreed on the necessity for this and on the general lines of policy which resolve themselves into:—

(a) arrangements for the continuation of malaria classes on lines approximating to what existed ten years ago, but under a more permanent organisation,

(b) arrangements for extension of the Malarial Department at Kasauli so as to form a definite and complete section of the permanent organisation,

(c) necessary building extensions at the Central Research Institute, Kasauli, to accommodate the proposed section and to allow of immediate expansion on the lines indicated.

"The malaria class was revived during June, 1925. For the future, we must look towards the creation of a field experimental laboratory or station in the plains, and enquiries are now being made with a view to a suitable location for the next class. Pending the erection of a permanent station on the lines of that on the Roman Campagna, temporary accommodation will be required to meet immediate needs.

"The permanent central malarial organisation should consist of an adequate staff, suitable buildings, and provision for contingent and other expenses. These have been elaborated in the note. Though it may not be possible to create this permanent organisation immediately, it might well be accepted in principle and worked to as financial conditions permit. From a technical point of view there can be no two opinions regarding the necessity for this staff if we wish to create a central malarial organisation commensurate with the needs of India.

"Had the Imperial Institute of Research at Delhi materialised as proposed, accommodation on more elaborate lines than that now suggested for the Central Research Institute, Kasauli, and for the field experimental station would have been made available. The present dearth of accommodation at the Kasauli Institute is highly unsatisfactory. Increasing activities in various directions have led to overcrowding, and the existing Entomological and Malarial Bureau are tucked away in an out-building, part of which is a central store. Here their present activities are hopelessly cramped and there is no room for expansion, whilst, in the main block, the library has overflowed into the corridors and the position is much the same.

"In the order of priority determined at Calcutta last November, expenditure on malaria came first. It is felt that if we move forward on the lines proposed, we shall be laying a sound foundation for the future campaign against this disease in India."

Lieutenant-Colonel Christophers then gave further details of the scheme. He concluded by saying that the Conference must decide whether it was satisfied or was not satisfied with the present organisation; if the latter, then it must make suggestions for the improvement of this organisation. He considered that there should be both a central and provincial organisations; provinces should be urged to help in the matter; the scheme which he had outlined was for the central organisation; it was only a provisional scheme which he would like to see altered for the better.

MAY, 1926.]

Lieutenant-Colonel Gill said that everybody would agree as to the economic importance of malaria in India. The proposal of Lieutenant-Colonel Christophers appeared to him to be a most important one. Did his proposals go far enough? Should there not be experimental stations erected in each province? Little work was now being done on the epidemiology of the disease. The question of *A. rossi* as a carrier had still to be settled. The main trouble up to the present had been lack of continuity in the organisation; he had got a malaria bureau equipped for his province but nothing outside routine work was done because he had no skilled officer to do the work. If such an officer were available much good work could be done. It seemed very important that there should be definite official collaboration between the central and the provincial organisations. Lieutenant-Colonel Gill hoped that a resolution on the subject would be passed.

Lieutenant-Colonel Dunn supported Lieutenant-Colonel Gill; he considered that the main work of the central organisation should be research work; he said that grants for a malarial organisation should be given to those provinces who helped themselves. Major Phillips said that in the United Provinces in the early days of the provincial malaria organisation between 1910 and 1914 a number of surveys were carried out in towns which were supposed to be malarious. The reports were transmitted to the central organisation, who, if they approved of the recommendations made, gave grants-in-aid to help in carrying out these recommendations. In 1923 some of the results were assessed; it was found that the existing malarial conditions varied according to the manner in which these recommendations had been carried out. A report was circulated and its effects had been very marked; members of the Legislative Council and Local Bodies had had their eyes opened as to the importance of the subject, and now large sums were being voted in the United Provinces for the control of malaria. He concluded by saying that what was wanted now was an expert officer to guide them as to how the money should be best spent. A general discussion followed.

After discussion a resolution was framed and proposed by Lieutenant-Colonel Christophers seconded by Lieutenant-Colonel Megaw and carried unanimously (*vide* Resolution 2, Appendix).

The Conference then proceeded to discuss the steps necessary for the co-ordination and promotion of medical research in India. Lieutenant-Colonel Graham opened the discussion by stating that, taking the research programme that had been approved by this Conference, there would probably be a credit balance this year of about half a lakh; it was for the Conference to decide whether in view of this fact they were justified in asking for the return of the full five lakhs grant-in-aid. A general discussion followed. Lieutenant-Colonels Dunn, Cunningham and Hodgson and Drs. Chandler and Brahmachari pointed out that research was still required in a number of diseases, such as cholera, pregnancy, anæmias, filariasis, blackwater fever; Major Taylor considered that there were many problems requiring solution, but that there was a difficulty at present in finding workers of the right type. Lieutenant-Colonel Megaw pointed out that the main obstacle to finding research workers was the fact that continuity of employment was not guaranteed. Lieutenant-Colonel Christophers said that the determining factor in the whole matter was the personnel. The matter of recruitment seemed to be an urgent one and should be discussed immediately.

Lieutenant-Colonel Hodgson considered that the trouble originated from the fact that an insufficient number of officers of the right type applied for admission into the Department because they were never interested in the subject of research; he considered that if more officers were sent to the Calcutta School of Tropical Medicine for training, more men would become interested in research work and from these men suitable officers could be chosen.

Lieutenant-Colonel Graham said that the Director of Medical Services in India was not in a position to give up all such officers. The matter had reached a point when they would probably have to recruit officers in the open market. Lieutenant-Colonel Fry asked whether it would not be possible to recruit officers for the Indian Medical Service on the definite understanding that they would be transferred to the Department at an early date. Lieutenant-Colonel Dunn suggested that certain officers might be seconded from the R. A. M. C. for research work for a short period. Lieutenant-Colonel Graham pointed out that 'seconding' was not possible and Lieutenant-Colonel Mackenzie spoke as to the shortage of officers.

Lieutenant-Colonel Christophers' resolution (amended) was read; it was seconded by Lieutenant-Colonel Megaw and carried unanimously (*vide* Resolution 3, Appendix).

Referring to the proposal to invite the Rockefeller Foundation to examine medical organization in India, Lieutenant-Colonel Cunningham asked why this invitation should be made. Lieutenant-Colonel Graham replied that, unless this invitation were offered by the Government of India, the Rockefeller Foundation would not consider the question of giving any financial assistance to any research institute or scheme in India.

Lieutenant-Colonel Megaw read letters from Dr. Heiser, dated 1923, on this particular point. Lieutenant-Colonel Megaw said that a few objections had been raised. The word "Commission" had been taken exception to; but there would be no obligation to undertake any of the suggestions if they were unacceptable. If London was not too proud to accept a million pounds from the Rockefeller International Health Board, surely India should not be too proud to accept help.

Lieutenant-Colonel Graham said that the Rockefeller Board had supported large schemes in Australia and that in this case certain stipulations had been made; he said that no friction had occurred as a result of the terms, and the whole scheme had been greatly to the benefit of the country and had accelerated the maturation of the present Ministry of Health.

Lieutenant-Colonel Megaw proposed a resolution which was seconded by Major Acton and unanimously passed (*vide* Resolution 8, Appendix).

A discussion then took place on how best to secure that the discoveries already made by medical research workers should be applied for the benefit of the people of India. Major Morison said that certain investigations were worked to a conclusion, but the matter went no further, as there was often nobody willing or ready to apply the results of the inquiry; an example of this failure occurred in connection with the guinea-worm research. It seemed desirable that a certain amount of money should be devoted to the application of research in order that the value of certain methods might be demonstrated to the population. Lieutenant-Colonels Bisset, Dunn and Gill entered into the discussion; they were of the opinion that it was a matter for the provincial health departments; the last named was of the opinion that the whole thing was a matter of education and that application of various methods should not go ahead of public opinion.

The President said that there was a principle involved which had been dealt with by the Scientific Advisory Board who had decided that the application of the results of research work on a large scale came outside the scope of the Funds of the Association.

Lieutenant-Colonel Graham said that he thought that experimental application on a strictly limited scale would be a proper charge on the Fund. Lieutenant-Colonel Christophers said that he thought it was often advisable for the application of research to be carried on at the same time as the research and Dr. Chandler considered that it was impossible to draw a line between research work in the laboratory and its application on a large scale in the field.

Lieutenant-Colonel Hodgson suggested that much could be done by educating the public and suggested that the publicity bureau be asked to press the matter of publication of resumé's of papers that appear in the

Indian Journal of Medical Research. In answer to this suggestion, Lieutenant-Colonel Graham pointed out that the publicity bureau and some leading daily papers always received a resumé of such papers as were considered suitable.

Major Morison suggested a resolution which, after redrafting, was proposed by him and seconded by Lieutenant-Colonel Christophers and unanimously adopted by the Conference (*vide* Resolution 4, Appendix).

Lieutenant-Colonel Graham then opened the discussion on the preliminary steps necessary to meet the occasion of the Far Eastern Association of the Tropical Medicine Congress in India in 1927; he said that it was not proposed that the Conference should enter into details but only lay down the general principles for the organisation of this Congress and he gave some excerpts from a letter from Tokio from Lieutenant-Colonel Mackie, and called on Lieutenant-Colonel Megaw to supplement this.

Lieutenant-Colonel Megaw said that he was present at the Congress held at Tokio in 1925; from a scientific point of view that Congress was in some ways rather disappointing as, on account of the enormous mass of material that was dealt with, it was impossible to hear even half the papers. He said that he thought we should be able to compete with the 1925 Congress from the scientific point of view; but he was afraid that, from a social point of view, we should have considerable difficulty in competing with them, as in Japan they had received lavish hospitality. The situation would be a difficult one, and he thought that it was essential that a whole-time officer should be appointed for at least one year before the Congress to deal with the situation; he felt that the honour of the Indian Empire was at stake. Lieutenant-Colonels Cunningham and Christophers, who had both attended one of these Congresses supported Lieutenant-Colonel Megaw's suggestion that an early start was of the utmost importance.

Lieutenant-Colonel Megaw proposed a resolution which was seconded by Lieutenant-Colonel Gill and adopted unanimously by the Conference (*vide* Resolution 7, Appendix).

Lieutenant-Colonel Cunningham said that experience at the International Malarial Congress at Rome showed that the malariologists of other countries were apparently unaware of the work which had been done in India on this subject. If this were true with regard to malaria, it was almost certainly the case with regard to Indian research work in general. Further steps were therefore required to 'broadcast' the work of Indian research workers:—

(i) By a further distribution of the *Indian Journal of Medical Research* amongst the research workers of other countries.

(ii) By a wider distribution of reprints by workers themselves.

The second method would appear to be preferable both on account of expense and efficiency. It would be cheaper in that only that part of the *Journal* which was of interest to any particular worker would be sent to him. A reprint makes a more personal appeal. Notice is therefore more likely to be taken of it. It is a more effective means of reaching those interested, because its distribution is in the hands of the author himself who is presumably more in touch with other workers on similar lines than those responsible for the issue of the *Journal* can be.

The prohibitive price charged for reprints by the present publishers of the *Journal* prevents any really effective circulation as far as most workers are concerned. It is suggested that assistance in this direction would be a proper charge on the Indian Research Fund.

Lieutenant-Colonel Ross's amendment was put to the meeting and carried by 15 votes to 5, and the original resolution was modified to meet the amendment and carried (*vide* Resolution 5, Appendix).

Lieutenant-Colonel McCarrison proposed a vote of thanks to the President.

The Conference was then declared closed.

APPENDIX.

RESOLUTIONS PASSED BY THE MEDICAL RESEARCH WORKERS' CONFERENCE IN DECEMBER, 1925.

1. The Conference after having discussed the research proposals put forward for the financial year 1926-27 both in their scientific and financial aspects, and having re-endorsed the priority research proposals of last year is of opinion that an ample case exists for the restoration of the full grant-in-aid of five lakhs.

2. The Conference is impressed with the great need for a permanent organisation for carrying out continuous and adequate investigation in regard to the prevention of malaria in India and strongly recommends to Government that a permanent central organisation on the lines proposed by Lieutenant-Colonel Christophers be early constituted.

The Conference also wishes to call attention to the necessity of creating adequate provincial malaria organisations working in collaboration with the central organisation and considers that the constitution of such organisations (*which should include at least one effective malaria worker*) ought to receive urgent and early attention by local Governments.

3. In view of the fact that whether from the point of view of adequately staffing of existing laboratories or of carrying on necessary researches in the field, the existing numbers of sanctioned appointments is inadequate, the Conference strongly urges the restoration to the pre-Inchcape numerical standard in the Research Department.

The Conference, having in view the fact that lack of sufficient first class research workers is already gravely interfering with the carrying out of urgently needed important researches in India, and is likely to become more acute in the future unless steps are taken to prevent this, is of opinion that workers of the required scientific status and experience should now be recruited, as circumstances dictate, from the open market.

In order to obtain the services of suitable men the Conference is of opinion that it will be necessary to give considerable thought to making such posts attractive both from the point of view of salary and of tenure of appointment and prospects.

The Conference is of opinion that this is an urgent matter and that steps of some kind should be taken at once.

4. This Conference, while recognising that the onus of carrying out the practical application of proved researches of public utility is a matter generally falling within the legitimate work of the various local Governments' public health departments, would yet insist that there are many experimental applications of research work which may legitimately be regarded as part of these researches, and that such, if considered on their merits, might suitably be eligible for being financed by the Indian Research Fund Association.

5. Seeing that it is a matter of great importance that the work of research workers in India be brought to the notice of workers of other nations and that the best means of achieving this is to encourage the distribution of reprints of publications in the *Journal* to the greatest possible extent, the Conference is of opinion that arrangements should be made for the issue to the authors of additional reprints at specially reduced rates.

6. This Conference re-affirms resolution No. 7 of last year's Conference* which was unanimous, and desires to impress on Government the fact that the health of the worker is of great importance in connection with any scheme for the improvement of agriculture in India.

(* Note.—Resolution No. 7 of the 1924 Conference runs as follows:—

"Proposed by Lieutenant-Colonel Megaw and seconded by Dr. Bentley:

That this Conference believes that the average number of deaths resulting every year from preventable disease in India is about five to six millions, that the average number of days lost to labour by each person

in India from preventible disease is not less than a fortnight to three weeks in each year, that the percentage loss of efficiency of the average person in India from preventible malnutrition and disease is not less than twenty per cent., and that the percentage of infants born in India, who reach a wage earning age is about 50 per cent. whereas it is quite possible to raise this percentage to 80 to 90 per cent.

The Conference believes that these estimates are under-statements rather than exaggerations, but, allowing for the greatest possible margin of error, it is absolutely certain that the wastage of life and efficiency which result from preventible disease costs India several hundreds of crores of rupees each year. Added to this is the great suffering which affects many millions of people every year.

This Conference believes that it is possible to prevent a great proportion of this waste at a cost which is small in comparison with the results obtained.

The recent census shows that the position in India is one of grave emergency. The Conference recognises that the problem is very complicated and involves not merely medical research, but also questions of public health, medical relief, medical education, propaganda, and social and economic considerations.

The Conference strongly urges on Government the immediate necessity for appointing a strong Commission, chiefly non-technical, for the purpose of making a thorough inquiry into the wastage of life and the economic depression in India which result from causes which are capable of being remedied.

The Conference believes that the greatest cause of poverty and financial stringency in India is loss of efficiency resulting from preventible disease and therefore considers that lack of funds, far from being a reason for postponing the enquiry, is a strong reason for immediate investigation of the question."

7. The Conference is of opinion that the forthcoming Congress of the Far Eastern Association of Tropical Medicine to be held in India in 1927 will necessitate a considerable preparation on the part of the Government and considers that in view of the time required for the various necessary negotiations, publications, etc., such preparations, etc., should be commenced at once. The Conference proposes that a provisional committee with a Secretary be at once formed to discuss and take early action in regard to the initiation of the organisations necessary in this matter.

The Conference is of opinion that a whole time worker with adequate staff will be required for at least twelve months beforehand and that arrangements for the Congress should be initiated at least eighteen months before the Congress meets.

8. The Conference strongly recommends to the Scientific Advisory Board that the Government of India be urged to issue an invitation to the Rockefeller Foundation to make a survey of medical education and research in India.

Some Pitfalls in Surgical Diagnosis.

By SIR HERBERT F. WATERHOUSE, F.R.C.S.
(Practitioner, Jan. 1926, p. 4.)

Acute Osteomyelitis is the commonest surgical condition in which diagnosis is most frequently not made until irreparable damage has been done. Sir Herbert has always been greatly interested in the disease, having produced it artificially, when working at the University of Gottingen in 1888-9, under the supervision of the late Professor Orth, by injecting pyogenic microbes into the veins of the ear in animals, and causing minor injuries to the bones.

There are two types:—(1) The ultra-acute type caused by the virulent *Staphylococcus aureus*; and (2) the type less violent in its onset, caused by *Staphylococcus albus*, *streptococcus*, *pneumococcus*, *Bacillus coli*, *Bacillus typhosus*, etc. The former type ought always to be diagnosed at the onset, because the symptoms are definite and unmistakable. In the latter type

an error in diagnosis is much more pardonable. In severe cases the initial symptoms will be a sudden rise of temperature to 103° or 104°F., often a rigor, intense toxæmia, vomiting, headache, and even delirium. In the milder cases the temperature may, at first, only be raised a degree, the constitutional symptoms may be scarcely noticeable, and in the case of the lower limb, the patient may be able to walk a short distance without much complaint of pain.

Acute osteomyelitis in an adult is not always of the relapsing variety, i.e., a recrudescence of the disease starting in childhood. In cases originating in adult age the disease more frequently starts about the middle of the shaft of a long bone, and not, as in children, at one end of the diaphysis. The cases in adults are almost invariably missed in diagnosis until pus reaches the periosteum.

Another common error is that the disease only occurs in the long bones. No bone in the body is exempt. It is not infrequently found in the ilium, the scapula, the flat bones of the skull, the sternum, and the os calcis. Acute osteomyelitis may follow a boil, an infection of the fingers, tonsillitis and pharyngitis; but the disease almost always occurs, not during the acute stage of the predisposing condition, but after it has subsided and is nearly forgotten.

In osteomyelitis the inflammation arising in the marrow frequently shows no signs of its presence except tenderness on deep pressure. The real reason for the condition being so frequently missed in its early stages, is that the practitioner expects to find the cardinal signs of inflammation present, viz., heat, redness, swelling, and pain. In the early easily curable stage of osteomyelitis there is no local heat, no tenderness, and no swelling. Pain varies in intensity and may be almost negligible. Osteomyelitis is frequently mistaken for acute rheumatism of the neighbouring joint but there is no effusion into the joint in the early stage of osteomyelitis, there is no superficial tenderness over the articulation as in inflammation of the joint, and the tenderness is either above or below the joint, not in the joint itself. The diagnosis should always be made within 24 to 36 hours, if necrosis is to be prevented.

A sudden rise of temperature, possibly a rigor, a feeling of malaise, a pain, which at first need not be severe, in a long bone just above or below a joint, and far more important, marked tenderness on firm, deep, and prolonged pressure over the site of the pain form the diagnostic features and it is dangerous to wait for further confirmation of the diagnosis. Given such signs it is the bounden duty of the medical attendant to have one or more openings made into the bone right down into the medullary cavity to relieve the tension and to save necrosis. Sir Herbert's advice is "Don't wait for a surgeon but take a gimlet or drill from a carpenter's tool-chest and, after boiling it, drill two or three holes into the bone yourself."

The bone ought to be drilled before pus has had time to form, and when only blood, swarming with staphylococci, or other microbes, oozes out.

Sub-phrenic Abscess.—This dangerous condition is generally missed. When, any time from two weeks to two months after a septic lesion in the abdominal cavity, a patient who has appeared to be well on the road to recovery develops continuous fever, elevation of pulse rate and malaise, and no definite cause can be found for the rapid deterioration in health, the possibility of a sub-phrenic abscess should be seriously considered. More than half of the cases seen by Sir Herbert have owed their origin to lesions of the appendix vermiformis. Next in order of frequency comes perforation of an ulcer on the posterior wall of the stomach into the lesser peritoneal sac. In this case the abscess is almost always under the left half of the diaphragm, those caused by appendicitis are practically invariably on the right side.

Percussion over the abscess is frequently most misleading. If the abscess is overlain with normal lung, percussion will give the normal note. If there be a basal pleural effusion the note will be dull. If the

abscess contains gas, as it frequently does, a tympanitic note will be elicited. Where possible an x-ray examination should always be made use of.

An effusion into the pleural sac caused by pleurisy, pneumonia, and empyema, or pulmonary infarct, starts suddenly with pain in the chest, and difficulty in breathing, whilst a sub-phrenic abscess takes days to develop, and is painless, certainly at the commencement.

A definite diagnosis of sub-phrenic abscess may only be possible by puncture with a needle of an aspirator; but this may only be done when everything is prepared for the drainage of the abscess. In a recent case pus was encountered only on the sixth insertion of the exploring needle. The practitioner must bear in mind the probability of a sub-phrenic abscess in cases in which, any time between two weeks and two months after any septic abdominal condition, the patient who has hitherto appeared to be making good progress develops a continuous high temperature, a constant quickening of the pulse rate, and a rapid deterioration of health, for which no obvious cause can be discovered.

The Period of Reaction after Perforation of a Gastric Ulcer.—In some instances of perforation of a gastric ulcer, a wonderful temporary improvement in the symptoms may occur before the graver signs of peritonitis develop, and this temporary improvement may be very misleading. When the surgeon can get no further in diagnosis than that of a very probable perforation of a gastric ulcer, immediate operative treatment is essential, because in every instance the lesion present has been either a perforated gastric ulcer or some condition equally calling for operative treatment. In perforation of a duodenal ulcer the period of reaction rarely shows anything like the same marked temporary amelioration of symptoms that is often noticed after gastric perforations.

Gangrene of the Appendix.—Sudden cessation of all symptoms and extraordinary temporary improvement may follow gangrene of the appendix. The late J. B. Murphy, of Chicago, once told Sir Herbert that "(1) The dead appendix ceases to absorb its noxious contents and, therefore, pulse and temperature fall to normal. (2) The nerves of the appendix are dead and, therefore, pain ceases. (3) Adhesions can only be formed between two living surfaces. The appendix being a dead thing, no adhesions will be formed to it and, therefore, there is the awful danger of diffuse septic peritonitis when the microbes pass through the gangrenous walls of the appendix, or it drops off."

Inversion of the Testis is hardly ever mentioned in the surgical text-books. Yet it has a considerable importance. In this condition the testicle is displaced, so that the epididymis is in front, and the body of the testicle behind it. The tunica vaginalis lies posterior to the body of the testis, and a hydrocele will, therefore, have the testis in front of it. It is not infrequent; in 100 adult men it was found present in three instances. Serious danger threatens when a hydrocele is tapped or operated upon in the case of inversion of the testis. When the general practitioner has to tap a hydrocele which is not translucent to transmitted light, he should enter the trocar on the outer side of the scrotum, instead of in front.

Prognosis in Cancer of the Breast.

By H. P. WINSBURY WHITE.

(*Practitioner*, Oct. 19, 1925.)

INFORMATION was obtained of 92 patients out of 120 who had been operated on at the Royal Free Hospital between 1900 and 1913. More than 50 per cent. of those traced died within 3 years of the operation, but over 20 per cent. survived for more than ten years. In two patients who survived more than 19 years the pectoral muscles were not removed. Altogether the more radical operation did not seem to give better results than the less thorough procedure involving only the breast and axillary contents, but the author does not advocate the incomplete operations because of the results shown in

a small series of figures. In 16 cases a preliminary excision of the tumour was made for diagnostic purposes; these cases did as well or better than the others, but presumably they were less advanced on the average as the diagnosis must have been in doubt at the time of the operation. Here again the author does not advocate exploratory excision except in really doubtful cases.

In all the cases in which death followed within 3 years there was either (a) fixation of the growth to the pectoral fascia or muscle; (b) fixation to the skin; (c) palpable axillary glands; or (d) microscopical evidence of growth in the axillary glands.

In the cases which survived for more than ten years these features were usually absent, in only one of them was there fixation of the growth to the pectoral fascia, but in several there were fixation to the skin, palpable axillary glands and in a few there was demonstrable carcinoma in the glands. The average duration of life was 3.6 years in the patients who had fixation of the growth to the pectoral fascia or muscle while it was 6.9 years in the remainder.

When there was proved metastasis in the axillary glands the average duration of life was 5.6 years compared with 6.1 years for the patients in whose cases metastasis could not be found.

More palpable enlargement of the axillary glands is no evidence of metastatic infiltration. Size of the growth in itself is not so important as would be expected, but the large growths are more frequently attached to the pectorals: when the growth is rapid there is a greater likelihood of visceral metastasis being established and the author suspects that these already exist in many cases at the time of operation. Skiagrams may reveal the larger, but cannot help in showing the smaller deposits. In several cases the growth was described as encephaloid; the prognosis in these does not appear to be any worse than in the others.

Modern Methods of Diagnosis.

(*Practitioner*, Jan. 1926, p. 1.)

IN the introduction to this special number, Sir Humphry Rolleston points out that laboratory methods supplement the diagnosis made by ordinary bedside examination, just as the microscope or the telescope increases the ordinary man's powers of observation. Physical signs deal mainly with the evidence produced by gross structural change, whereas laboratory methods not only may reveal structural changes, such as those in the blood, urine, cerebro-spinal fluid, and gastric secretions, which at best can only be guessed at by the unaided eye, but they may reveal the disorders of function which precede organic change.

There is a danger in relying too greatly upon the elaborate equipment possessed by every modern teaching hospital. Important as modern histological, hæmatological, bacteriological, and chemical examinations are in medicine, we must not over-estimate them or imagine that they make the older clinical methods of examination superfluous. Laboratory investigation must go hand in hand with the ordinary direct clinical examination of the patient.

Careful history taking and a thorough physical examination, with the exhibition of a due proportion of clinical acumen and common sense, serve the practitioner better than much laboratory lore. But the ideal is a critical judgment founded on the combined information supplied by the two methods, each serving as a supplement and check to the other.

The Virus of Tsutsugamushi Disease.

PROFESSOR NAGAYO and five other workers at the Government Institute of Infectious Diseases, Tokio (*Reports*, Vol. III for 1924), have described a virus which resembles Rickettsia bodies in connection with experimentally produced tsutsugamushi disease in monkeys.

In 1923 the same workers found that intradermal inoculation of the infected blood is most effective, resulting in a typical ulcer at the site of inoculation, whereas subcutaneous inoculation is never followed by ulcer formation. In tissues fixed with Orth's and Zenker's fluids and stained with azur II the large mononuclear cells of the skin of infected monkeys show numerous monococcal, diplococcal and short red forms of the organism in large numbers.

The virus is non-filtrable, non-culturable in the ordinary media and is transmitted in Nature only by a certain mite. The bodies are multiform and stain with difficulty. The bodies closely resemble those found in typhus fever and in the Rocky Mountain fever. The authors point out that the study of the Rickettsia bodies is incomplete, so that it is impossible to state that the bodies found by them are proved to belong to the Rickettsia group. If the virus of tsutsugamushi disease should prove to be similar to that of the other diseases of the typhus group, it will be possible to adopt the classification of these diseases which was provisionally suggested by Megaw, viz., louse typhus, tick typhus and mite typhus. From a clinical and epidemiological point of view this nomenclature has obvious advantages, it only remains to be seen whether it is justified on pathological grounds.

The Early Diagnosis of Disease of the Spinal Cord.

By SIR FREDERICK MOTT.

(Practitioner, October, 1925.)

THE first question to decide is whether we are dealing with a case of functional or organic disease, or a combination of the two.

A careful history of the onset and progress of the signs and symptoms should be made, noticing the mental attitude and behaviour of the patient; due regard being given to the fact that in hysterical cases there is always a danger of suggesting symptoms to the patient, especially in respect to sensory disturbances.

The onset is usually sudden, and the disability varies with the patient's emotional state, degree of attention, and the effects of external influences. After you have made a careful and methodical examination of the superficial and deep reflexes and found them all normal, you are justified in concluding that the paralysis, contracture, or inability to stand or walk (astasia, abasia), which may even have existed for months or years, is the result of auto-suggestion or hetero-suggestion, and you can then with confidence assure your patient that he or she can be cured. There is never unilateral increase of the deep reflexes, never genuine clonus, never a plantar extensor response. In functional cases, there is little or no wasting.

In functional sensory disabilities simulating spinal cord disease the superficial sensibility to pain, heat and cold, and touch, is lost completely; neither the anaesthesia nor the pains conform to the anatomical distribution of spinal roots or peripheral nerves. In the limbs the superficial anaesthesia takes the form of a stocking or gauntlet, and can easily be removed by suggestion, the restoration of sensibility being from above downwards. The secret of success in the treatment of these functional cases is faith; consequently, in the first treatment you must not leave the patient until you have established that by bettering or curing the disability. It may take minutes, it may take hours.

In patients who complain of pain in the spine test the reflexes, the sensory condition and ask about the sphincters, if these are normal and if movements of the spine are not attended with pain the condition is usually the result of suggestion.

Make a complete examination, mark down the site of the pain with a blue pencil, see whether the position cannot be altered by suggestion. If there is localized pain and tenderness which cannot be shifted by suggestion, organic disease is to be considered even in the complete absence of physical signs. Localized pain and

tenderness of the spine combined with a localization of pain in a skin area which corresponds to the same segment of the spinal cord are of great diagnostic importance in caries, new growth, aneurism, etc.

X-ray examination should be carried out in all such cases.

The pain of early cord disease may be neuralgic and variable in intensity, even paroxysmal: it is distinguished from true neuralgia by its segmental distribution. The pain of meningitis is often associated with local muscular rigidity and spasm, especially when the cervical region is involved. Lumbar puncture will often give the diagnosis in such cases.

Intercostal neuralgia and pleurodynia are often wrongly diagnosed in early disease affecting the nerve roots. Syphilis is a frequent cause of such root irritation.

The pain of peripheral neuritis is usually accompanied by tenderness on pressure of the calves and anaesthesia to light touch and the history will usually help. In all doubtful cases the Wassermann reaction should be carried out.

The pains of the pre-ataxic stage of tabes dorsalis are usually associated with the Argyll-Robertson pupil or with some inequality of the pupils, even if the knee jerks are still present.

Girdle pain is often an early symptom of focal meningitis or of progressive meningo-myelitis, the occurrence of this pain with paræsthesia should be the signal for active antisyphilitic treatment, to prevent the development of an incurable paraplegia resulting from complete transverse myelitis. In such cases lumbar puncture and the Wassermann test will usually give clear indications.

Abnormal sensation may also be caused by Raynaud's disease, arterial degeneration, neuritis, neurasthenia, etc. Short of actual pain, any feeling of numbness, tingling of pins and needles should arouse suspicion of organic disease and be followed by a thorough investigation, as they may be the earliest symptoms of myelitis or other organic disease. Total anaesthesia occurs only in cases of complete transverse lesion; dissociated anaesthesia is more common, loss of sense of a light touch may co-exist with unaffected deep sensibility.

In some spinal cord diseases sensory disturbances are transitory or even absent; in Landry's paralysis sensation may be unimpaired and the muscle electrical reactions may be normal: in anterior poliomyelitis there is fever, malaise, numbness and tingling in the limbs, soon followed by a flaccid paralysis and then wasting; the sensory disturbances are only transitory. In progressive muscular atrophy and amyotrophic lateral sclerosis there is no sensory trouble. Disseminated sclerosis though easy to detect in the well developed form, may easily be mistaken for neurasthenia when there are no cerebral manifestations.

Careful examination of the reflexes, especially of the plantar reflex will often give the diagnosis. The exact localisation of the lesion is very important in prognosis and in deciding on operation in the rare cases in which this is contemplated.

"More mistakes are made from not looking than from not knowing." Only a small percentage of cases complaining of pain in the spine suffer from disease of the spinal cord.

Blood Pressure in Diagnosis.

By SIR RICHARD DOUGLAS POWELL, Bart.,

K.C.V.O., M.D., F.R.C.P., D.Sc., LL.D.

(Practitioner, Jan. 1926, p. 42.)

A RELATIVELY high diastolic pressure indicates that with increased resistance the margin of heart-power is diminished. A high maximum with a relatively low diastolic pressure, i.e., a high pulse pressure, points to some defective support to the circulation as from impairment of aortic valves permitting regurgitation. Mental harassment and overstrain are the fruitful causes

of arterial tension. These are not uncommonly accompanied by irregular meals, rapid eating, dietetic indiscretions, and often irregularity or excess in alcohol. Premature arterial changes are observed in certain families. In case of high pressure the state of the gums and fauces must be examined for pyorrhœal or other septic conditions and the teeth looked to as a source of reflex irritation.

Defective function of the colon is also a frequent source of disturbance. Low specific gravity of the urine with raised blood-pressure suggests interstitial nephritis. A high specific gravity is less grave, suggesting excess of diet, defective exercise, etc., which can be corrected.

Alcoholic excess tends to lower pressure unless accompanied by organic changes, especially in the kidneys. Excess of smoking tends to raise blood-pressure in a spasmodic way.

Value of Examination of the Eye in Diagnosis.

By SIR RICHARD CRUISE, K.C.V.O., F.R.C.S.

(*Practitioner*, Jan. 1926, p. 23.)

Two instruments are needed by the practitioner, the binocular loupe and the electric ophthalmoscope.

Ptosis suggests third nerve paralysis of syphilitic or cerebral origin or myasthenia gravis.

Diffuse nebulae of the cornea if associated with remains of blood-vessels terminating at the scleral margin, detected by the binocular loupe suggest interstitial keratitis of syphilitic origin.

Phlyctenular ulcers suggest a toxi-tuberculous condition.

Localised nodules of the sclerotic suggest gouty, rheumatic or infective conditions.

No verdict should be pronounced upon a pupil till it has been examined with the binocular loupe—senile fibrosis of the iris or post-synechia from old iritis must be excluded. Unequal pupils are found in tabes and G.P.I. but a frequent cause is injury; so is pressure on the sympathetic from enlarged cervical glands.

The Fields of Vision can be taken effectively by standing straight in front of the patient at a distance of three feet; the patient has each eye in turn obscured; the observer has the opposite eye closed to that of the patient. The field of vision of the patient's right eye will correspond with the field of vision of the observer's left eye. The patient must fix, without wavering, the centre of the observer's pupil. A 10 mm. square of white paper on the end of a pen will readily elicit any gross defect. A central scotoma for small specks of colour, with full peripheral field of vision, suggests tobacco, alcohol, or diabetic poisoning, disseminated sclerosis, retinobulbar neuritis.

In paralysis of ocular muscles diplopia is the cardinal symptom. The ætiology of ocular paralysis is the ætiology of intracranial lesions, syphilis, vascular lesions, tumours, disseminated sclerosis, plus certain peripheral causes, such as diphtheria, "rheumatic" or infective conditions, associated with migraine—recurrent paralysis; it also follows injections into the spinal theca to produce anaesthesia. Injury is especially liable to involve the sixth nerve, which is not uncommonly affected after fracture of the base of the skull.

Nystagmus is a prominent symptom of disseminated sclerosis, cerebellar tumour, and labyrinthine disease; it affects miners as a form of occupation neurosis.

Examination of the fundus should be concentrated on the condition of (1) the optic nerve; (2) the blood-vessels; (3) the retina and choroid.

Papilloedema is seen as a marked striation of the margins of the disc with definite swelling and elevation of the nerve head above the plane of the retina. It is due to increased intracranial pressure; intracranial tumour of every description, hydrocephalus, meningitis (especially the tuberculous form), abscess, gumma, and neoplasm.

In optic neuritis there is a similar appearance of the optic nerve but the swelling never approaches the amount

seen in papilloedema; the retina is frequently involved, exhibiting cloudiness, hæmorrhages, and exudates (neuro-retinitis), the vision is greatly lowered, and the condition is frequently unilateral. The causes are toxæmia; syphilis, albuminuria, diabetes, influenza, and septic conditions in the mouth, nose, and throat, sinusitis, apical abscess of the teeth, etc.

In primary optic atrophy the disc margins are clearly defined, the disc is of a grey-white colour, and frequently the blood-vessels are unchanged. Tabes and G.P.I. are the usual causes, but the condition occurs in disseminated sclerosis, and as the result of pressure effects or injury. In optic atrophy secondary to previous optic neuritis, the disc margins are obscured, the physiological cup is filled in, and the vessels may have sheaths of fibrous tissue along them.

Arterio-sclerosis and high blood pressure can be diagnosed by sight; the thickened arteries can be seen to compress the veins where they cross each other, leading ultimately to obliteration of the lumen of the thin walled vein, and hæmorrhagic leaking along its course. Visible alterations in the calibre of the artery are diagnostic of arterio-sclerosis.

Syphilis, nephritis, and glycosuria are the principal causative agents of retinal inflammation. A diffuse cloudiness of the retina with optic neuritis and fine vitreous opacities will suggest syphilis. In albuminuric retinitis there is papillitis, congestion of the veins, flame-shaped hæmorrhages and white exudates in the peripapillary area.

In diabetes the changes are somewhat similar, except that papillitis is rare, the hæmorrhages are more frequently seen as discrete round spots, and glistening brilliant white patches and dots are of common occurrence.

Grossly disseminated patches of choroido-retinitis fringed with pigment are a frequent indication of syphilitic infection, whereas larger solitary areas of choroidal atrophy are suggestive of a tubercular origin.

The Value of Blood and Urine Examination in Renal Disease.

By HUGH MACLEAN, M.D., D.Sc., M.R.C.P.

(*Practitioner*, Jan. 1926, p. 67.)

THE estimation of the blood urea is usually carried out in the examination of renal patients. Many extra-renal conditions, such as cardiac disease, excessive diarrhoea, gastro-intestinal derangements, deep-seated abscesses and metabolic disturbances of various kinds may increase the blood urea. A high blood urea in itself is not a necessary indication of defective kidneys.

There is no increase in blood urea until about three-fourths of the normal kidney substance is rendered functionless; so that any information derived from blood urea estimation is confined to comparatively advanced cases of renal disease. Severe and progressive renal disease may be present without any protein appearing in the urine.

Albuminuria is present in about 3 to 5 per cent. of normal healthy adults. Many patients continue to pass albumin for very many years after an attack of acute nephritis, and yet functional tests prove that no evidence of nephritis is present. Whether albuminuria following acute nephritis is or is not associated with progressive kidney disease can always be settled by the use of modern functional tests. If any casual specimen of urine contains 2 to 2.5 per cent. urea or over there is very little the matter with the kidneys.

Many of the functional tests employed are not very difficult to carry out, yet they demand a certain amount of manipulative skill. Estimation of the amount of urea in urine, however, is an extremely simple process which can be carried out by anyone in a few minutes, and gives more information in general renal conditions than any other test at present employed. Instead of relying on albuminuria as an index of renal disease, the medical practitioner should get into the way of relying on urea concentration.

The Value of Modern Laboratory Methods to the General Practitioner.

By SIR FREDERICK W. ANDREWES, M.D.,

F.R.C.P., F.R.S.

(*Practitioner*, Jan. 1926, p. 17.)

CLINICAL pathology is growing yearly in its scope. Every large hospital has long been compelled to possess and equip clinical laboratories manned by trained workers in histology, hæmatology, bacteriology, and biochemistry. There are doubtless many of the older school who received their training in the days before clinical pathology was thought of who get along without it, trusting as they were taught to do, in their own clinical acumen and common sense. But the man of modern training, who has realized during his hospital career how much help pathological methods can afford in suitable cases, feels the want of them acutely in many a doubtful or difficult case.

A few men with a natural inclination for laboratory work become their own clinical pathologists. Many pathological examinations such as the staining of sputa, the examination of throat swabs for the diphtheria bacillus, and the Wassermann reaction, can be carried out quite well through the post provided that the practitioner is capable of furnishing suitable material. There are other investigations, such as the more elaborate blood examinations, in which postal transmission is unsatisfactory and really reliable results difficult to attain. Here, if the pathologist cannot be brought to the patient, the patient must be taken to the pathologist. The practitioner should understand the limitations of "pathology by post." There is the danger that it may degenerate into a "penny-in-the-slot" affair, in which the practitioner pays a small fee and expects his diagnosis by return of post. To a conscientious pathologist, lack of full details may be a serious handicap in the interpretation of the findings and he may not get from the examination all the help it might have been capable of affording. The practitioner should be so trained as to appreciate the help that clinical pathology can give. He should have been taught how to collect and transmit through the post the material required for pathological examination. He should know how to obtain a proper sample of sputum, free from buccal secretions; he should be able to take a faucial or pharyngeal swab, to take a syringe of blood from a vein, and to do a lumbar puncture; he should know in what fixing solution a portion of tumour should be placed on removal from the body. He should know, and trust, a pathologist whom he can take into his confidence. He should set forth a brief statement of the case and of the problem in which he requires help, with details of the nature of the material sent, and how and when it was obtained.

So valuable have modern laboratory methods proved, that the clinician, and perhaps especially the general practitioner, may be tempted to place too much reliance upon the pathologist.

Clinical pathology by post is one thing and treatment by post is quite another. It cannot too strongly be insisted that the results of laboratory methods, often carried out without actual contact with the patient, must be kept in due perspective as factors only, though often very essential ones, in the full review of the facts concerning any particular case. They can never replace, for example, the thorough physical examination of the patient of which the principles have been handed down to us by precept and example as the result of long clinical experience.

Skin Reactions in Asthma, etc.

By JOHN FREEMAN, M.D.

(*Practitioner*, Jan. 1926, p. 73.)

THE following is a list of protein idiopathies:—asthma, paroxysmal rhinitis, such as hay fever; animal

sensitiveness, such as horse asthma; food sensitiveness, such as egg-sickness; urticaria; eczema; ichthyosis; migraine-headaches; epilepsy; angio-neurotic œdema; paroxysmal arthritis, colitis or nephritis; etc.

All these are characterised by a specific sensitiveness to one or more foreign proteins.

Most of these protein sensitivenesses can *not* be tested for successfully, and many when detected are insignificant.

The skin-reaction is tested as follows:—If any cleaning of the skin is considered necessary, soap and water are preferable to an antiseptic. With any sharp sterile instrument, scratch through the superficial dead layer of the skin till the red cutis vera is laid bare, but avoid drawing blood.

A series of small areas, two to three millimetres square, must be scratched in this way, the number being at least one more than the number of tests to be made. The different protein reagents are then brought into intimate contact with the cutis vera on the different sites, one site being left untouched as a control. If the re-agent is a fluid, it is sufficient to drop it on the scratched area; if it is a dry solid, it may be rubbed into the scratches with any blunt instrument or dissolved in a slightly alkaline saline solution, and so dropped on to the scratch. If the protein is caught and dried on filter paper it may be stuck on to the scratched area with a drop of alkaline saline.

After the protein reagents have been in contact with the tissues for about five minutes, the scratched areas should be cleared up wherever necessary with swabs of wool and a little water, removing any blood, traces of reagents, paper, etc., which might obscure the reaction. This usually begins in about seven minutes with an erythematous blush, which surrounds the scratched area; following this an urticarial wheal starting at the scratch, but spreading beyond it into the surrounding skin. The reaction is at its height in fifteen or twenty minutes, and is usually fading rapidly in half an hour. We take as a positive reaction either a definite erythematous blush, or a definite urticarial wheal, or, better still, both of these together.

Occasionally the patient can tell you straight away that he has e.g. hay fever, horse asthma, egg-sickness, etc., and it is only necessary to confirm this by a direct test with, in these instances grass pollen, horse dandruff, and white of egg, respectively. Frequently, however, the patient can give no direct help, and it is highly necessary to get a clear idea as to what proteins to test for by thorough preliminary cross-questioning.

The reagents should be chemically identical with the foreign substances which are causing the symptoms in the patients; these various animal and vegetable substances need no preparation to make them produce a skin reaction.

A general practitioner had better begin by investigating in a small way with reagents culled from the kitchen or the world at large; frequently, almost usually, reactions obtained in this way are more definite and easier to read than reactions obtained with substances bought from a wholesale chemist.

If no reaction is obtained, this may be because the person is not sensitive to that particular reagent; but there may be other explanations. The reagent may have been spoilt in preparation; or it may belong to a group of proteins which give only slight or very doubtful reactions, e.g., the bacteria, moulds, and fungi in general.

If a positive reaction is obtained under suitable controls then the patient is sensitive to that particular protein, but this sensitization may be quite, or comparatively, unimportant as the cause of his illness.

Even after a dozen positive reactions have been obtained, there may yet be other and more important sensitizations which have not been detected or suspected. For example, it is no good to tell a man that his persistent asthma, urticaria, etc., is caused by eating bananas, tomatoes, or lobster, when the man has suspected and persistently avoided such food for years. It is useless to ascribe a rhinorrhœa in mid-winter to hay fever,

merely because the patient shows a positive dermal reaction to the pollen of the grasses.

Here the significance is merely that the patient is liable to random protein sensitiveness, and the important ones may be not easily tested for, e.g. microbic.

Skin Reactions in Diphtheria, Scarlet Fever, and Tuberculosis.

By A. B. PORTEOUS, M.D., B.S., D.P.H.

(*Practitioner*, Jan. 1926, p. 79.)

THE Schick test consists in inoculating into the skin of the subject a small measured dose of toxin, and observing what, if any, local reaction occurs. If no local reaction is produced, it is argued that the injected toxin has been neutralized by the patient's serum, and that the serum contains antitoxin, the amount of antitoxin being measurable by the amount of toxin injected.

The toxin is a six-day culture in sugar-free broth, filtered and allowed to stand 18 months to stabilize. The minimal lethal dose (m.l.d.) is estimated in the usual way. When required for the test a dilution is made so that one-fiftieth m.l.d. is contained in 0.2 c.c. This diluted toxin must be used fresh, as it is not reliable after twenty-four hours. A part of the diluted toxin is heated to 70°C. for five minutes, and is used as a control. In the test, 0.2 c.c. is injected very carefully intradermally, using an inoculation syringe with a fine needle. The control test is carried out on the corresponding spot on the other arm. A second syringe is used for this, and 0.2 c.c. of the heated toxin is injected here.

In positive cases the control arm is normal but on the test arm, after twenty-four to thirty-six hours, a red flush begins to appear. It is half to one inch in diameter, and is at its maximum in four days, gradually fading into a brown discolouration on which small scales may appear. Pigmentation may remain for weeks. Occasionally the positive reaction does not appear until the third day.

The negative and pseudo-reaction is a red flush with dark centre, less circumscribed than the positive reaction. It develops rapidly in twenty-four hours, and is equal on both arms. It has mostly faded by the fourth day, and may leave behind pigmentation with a certain amount of desquamation.

Positive and pseudo-reaction (combined).—The pseudo effect develops a red flush with deeper centre on both arms, and as this fades the positive emerges on the test arm as a much larger flush with a dark centre, which goes on to pigmentation and desquamation. The control reaction has meanwhile faded. The readings are most distinctive between the fourth and seventh days. The combined reaction is comparatively uncommon.

The patient is *immune* if the reaction is negative or negative and pseudo.

The patient is *susceptible* if the reaction is positive or combined.

Reviews.

THE PURPOSE OF EDUCATION.—By St. George Lane Fox Pitt. Fifth Issue, 1925. Cambridge University Press. Pp. 94. Price, 4s.

THIS thoughtful and scholarly book is one which should be read by all teachers and educationalists. Modern education, claims the author, is faulty in many of its directions, in both its aims and methods. We set out to teach school-boys or university undergraduates with an idea that we must make them practical persons, able to earn their livelihood. Hence our aims become purely materialistic; a fierce competition sets in, through

which indeed it is true that knowledge, skill and efficiency are to some extent acquired; but, with them, a permanent mental attitude towards life which is deplorable. Money becomes the world-ideal; competition the order of the day; and egoism the sole ideal of both men and nations, with the disastrous results of the great world war of 1914-1918.

The purpose of true education is not this at all. We may admit that the economic side of life is very important, but it is not all-important. It is the purpose of true education to develop personality, to foster high ideals, to lay stress upon the inter-dependence of one individual upon another, to develop character. It is not enough that a teacher should be clever and learned; a teacher can inspire in a pupil the love of learning for its own sake, only if he possesses it himself. The suppression of egoism and not its development should be the aim of education of the young. The teacher "should learn how and why beliefs, wishes and memories are related to one another, why they fluctuate, mingle and conflict. He should learn how and why our outlook upon life is so narrow and superficial; above all he should learn to know the true remedy for this pettiness, and he should love to apply that remedy." The belief that "we were meant to be happy," irrespective of all evidence to the contrary, is a delusion deeply implanted in our natures. In practice this delusion takes the form of insisting that we have a prescriptive right to the gratification of all our ephemeral wants. The truth is that, instead of postulating that we were meant to be happy, it should be the purpose of education to teach the student wherein true happiness lies and how to attain it. The man who is best educated is he who is of most service to his fellows. The alternatives are between the continuance of our present-day erroneous views as to the all-importance of money, with life governed by the morals of the jungle; and a realisation and inculcation of higher ideals and of nobler motives.

The matter is not unimportant. The development of personality and character in his students should be the aim of every sound teacher. And he will find in this admirable little book a most thoughtful contribution to this most difficult problem of the day.

It only remains to add that the volume is admirably published and wonderfully cheap.

MODERN MEDICINE.—By Many Authors. Edited by the Late Sir William Osler, revised by Thomas McCrae, M.D. and Elmer H. Funk, M.D. Vol. II. Third Edition. Pp. 891. London: Henry Kimpton, 1926. (Sold in sets of six volumes and desk index, £12-12 net.)

THE second volume of the new edition of Osler and McCrae is of special interest to medical men in the tropics, dealing as it does, with most of the great tropical diseases such as malaria, kala-azar, dengue, amoebic dysentery, relapsing fever, heat stroke, beriberi, hookworm disease, filariasis, etc.

Like all books which are written by specialists, each chapter bears the stamp of its author and the value of the work depends chiefly on the selection of the writers. Amoebic dysentery is dealt with by Richard P. Strong who has brought together a vast amount of detailed information and has written one of the most complete accounts of the disease in existence. His references to the work done by Sir Leonard Rogers and others in India are very complete, so it is all the more remarkable that Rogers' name is nowhere mentioned in the paragraphs which deal with emetine.

Malaria is discussed by Charles F. Craig in a very satisfactory manner; an interesting point is that the author describes the parasite of quotidian æstivo-autumnal malaria as a definite subspecies; in this matter he accepts the views of the Italian workers. Neither the coloured plates nor the stated points of distinction are very convincing, the size of the parasite appears to be the differential feature which is most strongly emphasized.

Craig's views on treatment are in accordance with the experience of most Indian observers, the dangers of intramuscular injections are duly emphasized. The chapter on blackwater fever is by Stephens. It is concise and to the point; the known facts are stated and space is not wasted on discussion as to the causation of the hæmolytic.

Kala-azar is discussed by B. C. Crowell in five pages in which the author has condensed the most important features of the disease. Even the aldehyde test is correctly described, a very unusual and gratifying feature in a general text book. The work of Knowles, Napier and Smith on the transmission problem had not reached the author in time for inclusion, and it is interesting to note that bed bugs, fleas, flies and mosquitoes are the insects which are described as having been studied. It now seems almost incredible that the sandfly should have escaped suspicion so long.

The chapter on syphilis is by the late Sir William Osler, J. W. Churchman, and L. A. Conner, whose names are sufficient guarantees of excellence.

The relapsing fevers are described by John L. Todd whose name is prominently associated with the early work on the African type. The differences between the tick-borne and the louse-borne varieties would justify separate descriptions or at any rate a clear statement of the differences between them; from this account the student will find it difficult to form clear ideas on this important point.

Special interest attaches to the article on beriberi by Musgrave and Crowell; it is a pleasure to read so rational and broad minded an account of the disease in place of the complacent dogmatism which is served up in all the other accounts of beriberi which have appeared in the text books of the past ten years.

The problem is stated to be "baffling" and "far from solved." "How many entities are included under the term tropical neuritis has not been sufficiently studied—until this has been done, beriberi must remain a clinical diagnosis of widely diversified meaning."

The authors italicize the following:—"It is not so easy to be certain that the food deficiency neuritis is all there is to the disease or group of diseases called beriberi."

When it is remembered that Crowell is responsible for these words and that he also was one of the workers whose human experiments are constantly quoted as evidence that human beriberi has been proved to be caused by a deficient diet, there are grounds for hoping that the beriberi problem may again be opened for discussion.

The attitude of "those in authority" has been one of contempt for the mentality of the people who dared to doubt the orthodox views on beriberi.

The article on pellagra contains a statement of the views of Goldberger; these appear to commend themselves to the author, Dr. E. J. Wood. The description of the disease is clear and concise.

Other chapters of exceptional merit are those on rheumatic fever by Poynton, animal parasites by Stiles, scurvy by Robert Hutchinson and rickets by Still. Despite the variations in standards of excellence of the articles in this volume, the reviewer is of opinion that it contains the best modern account of the groups of diseases with which it deals, and if, as can confidently be expected, the remaining volumes are as good, Osler and McCrae will retain its position as the best work on modern medicine.

A TEXT-BOOK OF MEDICAL DIAGNOSIS.—By James M. Andrews, M.D., Ph.D., LL.D., and L. Napoleon Boston, A.M., M.D. Third Edition. London and Philadelphia: W. B. Saunders Company, Ltd. Pp. 1422, with 555 illustrations, 21 in colours. Price cloth, 55s. net.

This third edition has been brought up to date by the inclusion of information with regard to a large number of tests and methods which have come into use since 1914 when the second edition was issued.

The previous edition was found useful by a large number of medical men and in the revised form the book ought to be still more acceptable. In the fourteen hundred odd pages there is a vast amount of information on methods of diagnosis, the illustrations are numerous and instructive. As is usual in books of this kind some of the paragraphs which deal with tropical diseases are less satisfactory than those which deal with cosmopolitan diseases.

In spite of these minor defects the book as a whole will be found a very valuable work of reference to the general practitioner and even to the specialist in medicine.

PRINCIPLES OF HUMAN PHYSIOLOGY.—By Ernest H. Starling, C.M.G., F.R.S., M.D., Sc.D., F.R.C.P. Fourth Edition. London: J. & A. Churchill, 1926. Pp. 1074. With 570 illustrations. Price, 25s. net.

PROFESSOR STARLING's well known and popular book "Principles of Human Physiology" has been before the profession for many years. In no other book is the subject of human physiology dealt with more clearly and lucidly and more comprehensively than in this volume. The author says in the preface that rapid advances in all branches of physiology have necessitated extensive alterations in every chapter and some parts of the new 4th edition have been entirely rewritten. In spite of this the book has not increased in bulk. Most of the recent advances in medicine are intimately connected with the advances in physiology and a book like this is not only essential for junior and senior students but should also form part of the library of every medical man.

ALLERGY, ASTHMA, HAY FEVER, URTICARIA AND ALLIED MANIFESTATIONS OF REACTION.—By William W. Duke, Ph.B., M.D. St. Louis: The C. V. Mosby Co., 1925. Pp. 339. Price, \$5.50.

THIS book is intended by the author to give a simple and brief account of this important subject. The author's experience of the study of hypersensitiveness is almost entirely clinical and he has presented the subject from that view-point. In the first four chapters the author deals with the subject of experimental anaphylaxis and discusses the difference between the physiological reactions of different animals as the result of anaphylactic insult. In the subsequent four chapters serum sickness, bacterial allergy, natural hypersensitiveness of human beings and its relation to other diseases are discussed. A comprehensive botanical survey of pollen-bearing plants of Kansas City is found in Chapter X, with a large number of illustrations. After discussing a variety of things to which the individuals show sensitiveness, their contributory causes and the symptoms of the reaction produced, he passes on to specific diagnosis. In Chapter XV, methods of making skin tests and their interpretation are described, and the subsequent chapter deals with the specific and non-specific treatment of these conditions.

Part II of the book is devoted entirely to the reactions caused by physical agents such as light, heat, cold, mechanical irritation and the sensitiveness of the individual to these is discussed. The author has accumulated a large number of interesting facts obtained from his clinical experience which lend the book a considerable interest and make it well worth perusal by those interested in this subject. The bibliography at the end of the book gives references to a large number of papers bearing on the subject.

DIABETES MELLITUS AND ITS DIETETIC TREATMENT.—By B. D. Basu, Major, I.M.S. (ret'd.). Thirteenth Edition. Allahabad: The Panini Office, 1925. Pp. 94. Price, Rs. 2.

ALTHOUGH this book has undergone several editions and the author has deservedly won distinction by his numerous contributions to medicine, biology, history, and the sacred literature of India, we are greatly disappointed to see the 1925 edition of this book bereft

of all information regarding the marvellous modern development in the diagnosis and treatment of the disease. As in former editions he continues to describe methods of treatment, physical, medicinal and dietetic, many of which are obsolete and others not based on scientific proofs. In a book of 94 pages the learned author has thought fit to devote 15 lines only to insulin! We cannot recommend the book to our readers, but hope that the author will revise the book and make the next edition more up-to-date.

A PRACTICAL MEDICAL DICTIONARY.—By Thomas Lathrop Stedman, A.M., M.D. Eighth Edition. London: Baillière, Tindall & Cox, 1925. Pp. xii plus 1146. With 11 plates and over 400 figs. Price, 35s. net.

THIS beautiful volume is the eighth edition of a work which is well known to the whole English speaking medical world.

A large number of new titles have been introduced without adding greatly to the size of the book. On glancing at the pages it would seem impossible that any name of importance could have been overlooked, but even "Homer nods" and the reader is disappointed to find that some well known names in Indian medicine have been overlooked, such as *kurchi*, urea stibamine, etc. Apart from such omissions we have found the definitions to be satisfactory and complete. The book will be found to be a valuable addition to the physician's library.

THE EXTRA PHARMACOPEIA, VOL. II.—By W. H. Martindale, Ph.D., and W. W. Westcott, M.B. Eighteenth Edition. London: H. K. Lewis & Co., 1925. Pp. xiii plus 728. Price, 20s. net.

WE must apologize for the regrettable delay in reviewing this very valuable little book. The *Extra Pharmacopœia* is too well known to need any special recommendation. This eighteenth edition fully maintains the high standard of excellence which has been set by its predecessors, it has been brought up to date by the inclusion of references to all the work which has been done on drugs since the preparation of the previous edition.

The work is far more than a mere compilation, its editors have been in the forefront of research work on drugs: their own investigations have been incorporated and the work of others is dealt with in a critical manner. It is most regrettable that Dr. Wyn Westcott died while the book was being printed so that this is the last edition which will benefit by his experience and extensive knowledge. In less than 800 pages a remarkable amount of information has been condensed and it is not likely that the medical man will fail to obtain information of a reliable kind with regard to any drug or any method of treatment in which he desires information. It is a book which is essential to every practising physician.

FOOD AND HEALTH.—By Ruth Young, B.Sc., M.B., Ch.B. Lahore: Guran Ditta Mal Kapur at the Kapur Art Printing Works, 1925. Pp. 88.

THIS little volume of 88 pages tells all that the average person ought to know about food. The language for the most part is simple and free from technicalities.

The booklet is suitable for senior school children and for educated people in general.

BABIES.—By A. G. G. Thompson, M.A., M.D., D.P.H. London: Humphrey Milford, Oxford University Press, 1925. Pp. 32. Price, Re. 1.

THIS little brochure is an altogether admirable one for the expectant mother and mother. In simple language it deals with the ordinary problems of maternity from a non-technical standpoint. The expectant mother is counselled to consult her medical adviser twice during pregnancy; once within the first three months, to ward off such dangers as eclampsia, osteomalacia and the like; the second time towards the termination of

pregnancy, in order to ascertain that the presentation is likely to be normal and that everything is straightforward.

With regard to feeding of the infant, the author insists upon three-hourly feeds during the day, and none at night. The baby should always be awakened up to be fed during the day time. At two months of age the feeds should be given four-hourly; and it is important that at each feed only one breast should be emptied, and the other left to refill. At six months the first crust of wholemeal bread should be given. Dummy teats the author rightly condemns entirely.

Successive chapters deal with the bottle-fed baby, in which simple formulæ are given for citrated cow's milk; with washing and bathing the baby, special emphasis being laid on having everything ready beforehand, so as not to expose the infant to cold for too long; with clothing, where loose open clothing is advocated, and the use of two napkins, the first a thin one to fit tightly, the second a loose one to cover the first; and above all, with the necessity for fresh air and sunlight in abundance. Chapters on personal hygiene and the habits of babies are both excellent and full of practical instructions for the young mother.

The whole little brochure is exactly what should be in the hands of every mother and expectant mother. It is written in simple language, and full of information of practical value.

Annual Reports.

REPORT OF THE HEALTH OFFICER OF CALCUTTA. 1923. BY H. M. CRAKE, M.D., D.P.H. CALCUTTA: CORPORATION PRESS. 1925.

THE number of deaths registered during the year was 25,824, equivalent to a death rate of 28.5 per thousand calculated on the census population of 1921. This is a slight improvement on the returns for 1922 when 26,381 deaths occurred, the death rate being 29.1 per thousand. There has been a steady and uninterrupted fall in the death rate of the city for four years in succession, viz., from 42.2 per thousand in 1919 to 28.5 per thousand in 1923. Though still higher than in 1916-17, the years preceding the terrible epidemics of influenza, the death rate now corresponds very closely to the average rate recorded from 1910-1915.

Local variations in death rate.—The lowest rates were recorded in wards 16 and 17; these wards consist mostly of better class European houses. The highest rates are recorded for ward 19, Entally; ward 20, Beniapukur; ward 21, Ballygunge; and ward 24, Kidderpore.

The death rate amongst females is very much higher than amongst males, the rates are 38.8 and 23.6 respectively. The difference is much more marked in certain wards, for example in wards 14 and 8, Taltollah and Colootolla, the rate amongst females is more than double that amongst males.

Infantile mortality.—This is as usual very high. A slight increase is recorded since last year; this year's rate is 294 per thousand births registered. The difficulty about gauging the infantile death rate is that it is dependent not only on all the deaths being registered but on all the births being registered also; it is a much more difficult task to get the latter carried out. The infantile mortality was highest in ward 5; the population of this ward is almost entirely Hindu. In four out of the five other wards that show a high infantile mortality the population is almost entirely Moham-medan.

This high infantile death rate is due largely to poverty, with the consequent ill-feeding of expectant women, but at the same time bad housing, child marriage, the purdah system, disease and ignorance all combine to undermine their health. Although many premature

births result from the conditions noted above there is no doubt that a large percentage are due to syphilis. Making allowances for the fact that chronic malaria is an important factor in the causation of premature delivery, the large number of stillbirths is evidence of the widespread prevalence of venereal disease. More than half the deaths amongst infants occurred during the first month of life. The main causes of death were tetanus neonatorum, respiratory diseases and debility. Tetanus neonatorum, a disease which is entirely preventable and is caused by dirty midwifery, was responsible for 386 deaths. The comparative rarity of deaths from diarrhoeal diseases is noteworthy; this is due to the fact that almost all children are breast-fed and that it is only when they are taken off the breast that these conditions appear. The infantile death rate has increased appreciably amongst both Indian Christians and Anglo-Indians. Can this be due to increase in unemployment amongst these classes?

Birth rate.—There is a slight increase in the number of births that were registered during the year.

Plague.—There was a mild recrudescence of plague, to which the term epidemic can scarcely be applied; 77 deaths, or almost half the number recorded for 1922, occurred.

Cholera.—The epidemic of cholera is one of the mildest that has been recorded for some years, 914 or only 48 more deaths were recorded than during the year 1917.

Small-pox.—A comparatively localised outbreak occurred; only 157 deaths were recorded.

Influenza.—There has been a steady fall in the number of deaths recorded from influenza during the last five years; this year only 371 deaths are recorded.

Tuberculosis.—There has been a decided fall in the number of deaths recorded as from tuberculosis, which is very satisfactory in view of the fact that there had previously been a steady increase in the number of deaths recorded since the year 1917. On the other hand there has been a slight increase in the number of deaths from dysentery and enteric.

Malaria.—As diagnosis is not always to be relied upon it is better to consider deaths from malaria and from other fevers together. As one would expect, the two most rural wards show the highest rates, Ballygunge is the highest and ward 20, Beniapuker, is the next.

Respiratory diseases.—There is a slight increase this year in deaths from respiratory diseases. The suburban wards show the largest number of cases. One would expect that the poor bustee dweller, ill-clad and poorly fed, living in a damp mud-walled hut would be most susceptible. The highest rates occurred in the months of January and December.

Kala-azar.—The mortality from kala-azar, which has been increasing steadily for several years, shows a sudden and very marked rise this year. The number of deaths due to this cause is given as 501 or 0.55 per thousand. A very large number of the cases are imported, but making allowance for these, there seems to be little doubt that kala-azar is becoming more prevalent in Calcutta.

Dengue.—A severe and widespread epidemic of dengue spread through the city during the months of August, September and October. All classes of the community were affected, and it is estimated that 30 per cent. of the population were attacked. This means that there were about 300,000 cases. Only a few months before the onset of the epidemic the mosquito brigades were disbanded despite the protests of the Medical Officer of Health.

Epidemic Dropsy.—Four groups of cases of epidemic dropsy were reported during the year. These outbreaks were investigated by Lieutenant-Colonel Megaw at the School of Tropical Medicine. A conference was held at the School and certain conclusions with regard to this disease were arrived at; these are stated briefly below.

(1) Epidemic dropsy is undoubtedly caused by eating rice. It has never been known to occur amongst persons who do not eat rice.

(2) Recent experimental work at the Tropical School has shown that rice which has been stored for some time under certain conditions of temperature and moisture is attacked by a fungus or bacterium, and a toxin is formed which, when extracted and injected into animals, is capable of producing all the symptoms of the disease.

(3) The actual organism has not yet been isolated.

(4) It is not possible at this stage to assert that a particular sample of rice will cause epidemic dropsy without elaborate pharmacological tests on animals. That is to say the seizure and destruction of rice suspected of causing epidemic dropsy as unfit for human food is hardly practicable at this stage.

(5) On the first appearance of symptoms of the disease absolute stoppage of rice and a mixed diet rich in vitamins, e.g., fresh milk, eggs, ghee, butter, fresh vegetables, fish, meat, etc., not only prevents the further development of the disease but effects a perfect cure.

(6) As a preventive measure the use of freshly prepared rice is strongly recommended.

ANNUAL REPORT AND STATISTICS OF THE GOVERNMENT GENERAL HOSPITAL, MADRAS, FOR THE YEAR 1924. MADRAS: SUPDT., GOVT. PRESS, 1925. PRICE RS. 6.

The total number of persons treated in the out-patient department during the year was 62,050, of which nearly five thousand were Europeans; the average daily sick was 380. The total number of in-patients was 9,648; this is again an increase over last year. A steady increase in the number of non-Europeans treated in the hospital has occurred during the last six years.

The report of Lieutenant-Colonel Elwes, the 1st Physician, includes some interesting comments on cases which are given below:—

1. *A Case of Malaria simulating Tetanus.*—P., aged 40, was admitted on 1st September, 1924, with a history of fever on alternate days. Examination revealed a palpable spleen and benign tertian parasites in the blood. The patient was put on to purgatives, followed by quinine. On the third day he was found with trismus, stiffness of the neck, ptosis of the left eye and difficulty of swallowing; there was no spasm of any other muscles. The blood was again examined and parasites again detected. Complement fixation test for tetanus could not be done; Schick's test was negative. The patient was put on intravenous injections of quinine bihydrochloride grs. 10, and anti-tetanic serum 20 c.c. a day. This treatment was continued for 5 days; the tetanic symptoms disappeared, the serum was stopped and quinine continued by mouth. This must evidently have been a case of malarial toxin affecting the central nervous system, particularly the nuclei of fifth and seventh nerves and producing symptoms akin to tetanus.

2. *A Case of Encephalitis Lethargica developing in the Course of Broncho-Pneumonia.*—J., aged 19, student, admitted on 7th August, 1924, with a history of fever and cough for eight days. Examination revealed pneumonic patches in both lungs; the blood contained no parasite, but showed a polymorphonuclear leucocytosis; the patient was treated as a case of pneumonia.

Two days later the patient was found to be rather lethargic, answering questions very slowly; there was a certain amount of ptosis of both eyes and some rigidity of the limbs. Reflexes were elicited with difficulty. Ophthalmoscopic examination showed that the retina and discs were normal. Lumbar puncture was done but no fluid drawn out. The pneumonia was cured in a fortnight's time but the lethargic state persisted and the condition was diagnosed as encephalitis lethargica. The patient remained for a month more in the ward; the lethargic condition remaining stationary. Discharged on 21st September, 1924.

In this connection it may be mentioned that two other cases of encephalitis lethargica were treated in Colonel

Elwes' wards during the year; one from Coimbatore and one from Guntur. In both, the disease developed after an initial attack of fever lasting a fortnight. Treatment was of course unsatisfactory.

Undulant fever.—Another interesting case was one of undulant fever. The patient was a Forest Officer, aged 36, who was in the United Provinces for a short time some years back and states that he used goat's milk for a month in the forest. Fever developed in April, 1924, and the patient was first treated with quinine in the district as a case of malaria. Not improving, he came to the General Hospital in July 1924 and on admission he was found slightly anæmic, with enlarged spleen and high fever. The fever was found to be irregularly remittent in type. He gave a negative result to all the usual tests, and finally an agglutination test for *Micrococcus melitensis* was tried and a positive reaction of 1 in 1600 obtained. Culture of blood and urine did not reveal the organism. He developed sciatica twice in the course of four months, each time in a different leg. This case was still under treatment.

Kala-azar and Its Treatment.—Antimony tartrate is still the most satisfactory drug, according to Colonel Elwes, in the treatment of kala-azar. In a few cases 5 c.c. of a 2 per cent. solution were tried every other day instead of higher doses at longer intervals. These cases were not found to progress quite satisfactorily, so that the 5 c.c. method was given up, and higher doses given in all cases. In two cases which were found very resistant, sodium antimony tartrate was tried, and marked improvement resulted. In some of the advanced cases of kala-azar it was observed that the vein walls were degenerated and effusion of blood occurred into the surrounding tissues with the first injections of 2 per cent. solution of antimony tartrate. Such cases are now started with a 1 per cent. solution for the first few injections, substituting the stronger solution later on.

The great tendency of kala-azar cases to develop lung complaints with increasing doses of antimony tartrate is still the embarrassing feature of this treatment; the lung complaints being mainly broncho-pneumonia and lobar pneumonia; in one case pleurisy developed. The antimony treatment had to be temporarily stopped for a while in these cases. The patients were none the worse for these complications and the spleen diminished more rapidly subsequently.

Diabetes and Insulin.—Insulin has been tried in eight cases. As much as 120 units have been given in a day to a patient. Certainly it improves the condition of the patient: hyperglycæmia and glycosuria as well as ketone bodies disappeared; patients could take more carbohydrates, and their weight increased, but the improvement depended upon the continuance of insulin injections. When insulin was stopped or the quantity appreciably decreased, the symptoms reappeared. It is still in the trial stage and a definite opinion cannot be given now.

Some interesting cases were reported by the 2nd Physician, Major G. E. Malcomson, I.M.S. He reported two cases showing unusual clinical manifestations of a benign tertian malarial infection:—

An Indian male, aged about 35, was admitted for stiffness of, and inability to open the lower jaw. There was no fever for one or two days after admission, the temperature then taking on a sub-febrile course. Benign tertian parasites were then discovered and the masseter spasm was only relieved after the administration of quinine.

An Indian male, aged about 25, was found in a collapsed condition in a railway carriage with choleraic motions. He was admitted into the General Hospital almost moribund. As his temperature was found to be slightly raised and his spleen enlarged a blood film was taken; this was found to be teeming with benign tertian parasites. It was noticed that the conjunctivæ were slightly jaundiced before death.

Post-mortem.—All the organs were found to be stained with bile. The bladder contained dark-brown urine which spectroscopically showed bands for reduced

hæmatin and hæmoglobin but no bile or bile salts. The liver and spleen were much enlarged, weighing 76 and 30 ounces respectively. The former showed dilated intralobular capillary spaces and heavily pigmented Kupffer's cells; slight round celled infiltration in Glisson's capsule in the neighbourhood of the portal area but no increase of interstitial tissue.

The spleen showed dilated sinusoids with endothelial proliferation and pigmented phagocytic cells; increase of connective tissue was observed.

Microscopic examination of the intestines showed no abnormality; no parasites were observed in the intestinal capillaries.

Nine cases of tuberculosis of the lung were treated with Dr. Bruschetini's sera and vaccines kindly supplied by Signor Martirosi, the agent for these preparations in India. Of these, four were cases of open tuberculosis, of which two were apparently cured; five were closed tuberculosis of which four were apparently cured. All cases showed lung involvement by x-ray examination.

The following case is of interest as illustrating the permanent effects of lightning shock on the nervous system.

The patient, a Hindu student, aged 23 years, came to the hospital complaining of weakness of the legs following a lightning stroke some two years ago. He gave the following history:—He was standing with bare feet on a bare earth-floor (? stone floor) of a temple during a thunder-storm. The only clothing he had on at the time was a loin cloth. He states that his skin, his clothing and the ground were all dry at the time of accident. The roof of the temple was made of copper plates. This was struck by lightning but apparently not seriously damaged. He was struck at the same time and lost consciousness at once. He remained unconscious for three or four hours and was unable to speak for some three hours after regaining consciousness. On trying to stand up his knees gave way under him, and it was some six months before he was able to walk properly. A certain amount of weakness still persists. The right side of the body was partly burnt by the shock, for he now presents a diffused scar on the right shoulder and on the outer surface of the right thigh.

The patient is a well-built healthy looking man of 23. The motor power of his lower extremity is slightly diminished, that of the upper is apparently normal. Muscles of the face are unaffected.

Pupil and abdominal reflexes are normal; the elbow and biceps jerks are brisk on the right and apparently normal on the left. Knee and ankle jerks are exaggerated, more so on the right side. Plantar reflex is always extensor on the right side, on the left side variable.

Cutaneous sensations are all normal with the possible exception of slight impairment to heat and cold in the extremities. There is no nystagmus, no intention tremor, no marked ataxia, but Romberg's sign is distinctly present, the patient losing his balance at once.

Dr. M. R. Guruswami, the 4th Physician, reported the following cases:—

Post-encephalitic Parkinsonian Syndrome.—There were 5 cases under this group. Two only are given here in some detail.

A, Indian student, aged 23, male, was admitted on 23rd August 1924 for "inability to speak well and slowness of movements." In June 1920, he had a short fever for 3 days, characterised by diplopia and sleepiness—a sleep from which he could be temporarily roused with difficulty. He was treated for a few days at Vizagapatam Hospital and later had recourse to Ayurvedic treatment. He says he improved somewhat. A little later, he was unable to speak, or keep awake; his movements became sluggish, even mastication was found difficult. There was ptosis of both eyelids for a short time. After a month he began to recover slowly, though the improvement stopped at the condition found at the time of admission.

Condition at time of admission.—He had a mask-like expression, slightly parted lips with dribbling of saliva. Left facial muscles feebler in tone than the right; other

cranial nerves apparently not affected; neither strabismus, ptosis, nystagmus nor diplopia. Accommodation and light reflexes were sluggish; the grip was quite good; there was slight spasticity of the lower limbs but no tremors—intention or otherwise. The abdominal reflex was very marked. Babinski's sign and Romberg's sign were absent. Plantar and other superficial reflexes were exaggerated. Knee and ankle jerks were exaggerated. In short, defective speech, slow movements, dribbling of saliva, inability to walk well or keep the head erect while walking, coupled with an "ironed-out face" characterised the patient at the time of admission. The deviation from the picture of paralysis agitans is evident from the description given above and this deviation has been attributed by various writers—J. C. McKinley (1923), Goldstein (1922) and others to their finding in such cases diffuse toxic lesions not in the globus pallidus and other basal ganglia, but in the substantia nigra and in the nuclei and paths nearer the spinal cord than the globus pallidus itself.

"The question how the toxic matter arises will have to be investigated when more cases come in. Whether we are dealing with a toxin produced directly by the virus of epidemic encephalitis or whether the liver is primarily affected and liberates toxins which injure brain matter are questions for future investigation, with the aid of more advanced students than I have now. Why some patients develop these sequelæ, while others do not, whether there is anything peculiar in the constitution or brain of some that makes them more prone to develop these phenomena are interesting points to be considered by the maturer physicians.

The patient showed a distinct improvement on hexamine by the mouth as well as intravenously."

Another case.—S., aged 21, male, admitted on 8th March, 1924 for tremors and indistinct speech. The chief signs that he showed were fine tremors of fingers increased on attempting to use the hand, slurring speech, nystagmus, divergent squint, the pupil of the left eye dilated while that of the right eye was contracted, optic disc paler than normal with well-defined margins. There was no incoordination, and no Romberg's sign or Babinski's sign. The knee jerks were exaggerated.

He gave a history of continuous fever for one month in 1921. A day before the onset of fever squint was noticed and he was delirious for 10 days during that illness. Diplopia developed during the pyrexial period and tremors and slurring speech followed.

Spleno-medullary leucæmia.—S., aged 40, admitted on 28th June, 1924 for a tumour of the abdomen, numbness of feet, hands and mouth of 7 months' duration. The patient looked very anæmic, with spleen extending well below the level of the umbilicus. The history of his illness was interesting:—About 8 months prior to admission, he had a fall from the roof of a house and was unconscious for 5 minutes. He had severe pain in the lumbar region, of a gripping character, for about a week after that. Gradually it wore off under local treatment. A month later, he noticed for the first time a small, hard tumour under the costal margin and this had been steadily increasing in size. Occasionally he got slight fever, specially towards evening. The bowels were constipated and there was distress on taking food. His motions showed no helminthiasis.

Blood examination on 1st July 1924 showed R. B. C's. 2,137,500, hæmoglobin 44 per cent. and W. B. C's. 302,000. The differential count showed 15.4 per cent. myelocytes, 21 per cent. large mononuclears, 15.4 per cent. lymphocytes, and 2.1 per cent. eosinophiles. Nine megakaryoblasts and six normoblasts were also met with during this differential count.

Arsenic internally and x-ray exposures to the spleen were given with the result that on 3rd September 1924 when he was discharged he had 3,500,000 R. B. C's. and 30,000 W. B. C's.

"Globulin test.—Finding from last year's experience that liver puncture was somewhat risky, I tried to do without it in diagnosing kala-azar and had to depend (when the peripheral blood did not yield parasites) on

the ratio of R. B. C's. to W. B. C's., leucopenia and mononucleosis and the aldehyde test, put together. Incidentally I tried to find the value of the globulin test or Brahmachari's test by examining one hundred consecutive cases admitted into my wards. The result was very disappointing and I have concluded that this test is of no value as an aid to diagnosis. The reaction was positive not only in kala-azar, but also in such widely different diseases as capillary bronchitis, influenza, pernicious anæmia, nephritis, malaria, myocarditis, bacillary dysentery, biliary colic, cirrhosis of the liver, pneumonia, rat-bite fever, abdominal tuberculosis, and ankylostomiasis. At the same time I must state that amongst influenza cases three gave a positive and eight negative results; amongst malaria cases five gave a positive and six negative results, and amongst cases of cirrhosis of the liver two a positive and three negative results. A large number of cases suffering from other diseases gave negative results."

The Honorary Physician, N. Venkataswami, reported the following cases:—

"Angina pectoris due to malaria.—A patient was admitted on 5th February 1924 with a history of acute pain over the left side of the chest, radiating down the left arm to the tip of the little finger. The attacks were of irregular onset without any relation to undue exertion. The protracted and not very acute nature of the pain during the attack on admission made me label it 'pseudo-angina' which only meant that the cause was not known. A slight temperature of about 101° on certain evenings roused my curiosity to examine the blood when M. T. rings were found rather easily. The relief of pain experienced and the absence of the same after treatment with quinine made me infer that malaria might have been the cause of the angina pectoris.

Ascites probably caused by chronic bacillary dysentery.—I am inclined to believe that there are many cases of ascites, usually regarded as being caused by portal cirrhosis of the liver, which are really the result of chronic peritonitis secondary to bacillary dysentery. This view is based on the belief that cases of ascites due to cirrhosis of the liver do not survive many tapplings and from the fact that ascites apparently of the type due to alcoholic portal cirrhosis of the liver is found in many total abstainers from birth. A case of ascites was admitted into my wards on 16th June 1924 that did not give any history of alcohol. I had no reason to doubt that statement. A history of previous dysentery and a few previous tapplings of the abdomen was elicited. There was not the characteristic facies of ascites due to cirrhosis of the liver; neither did the abdomen fill up rapidly after he was tapped a few days after admission. I am inclined to believe that this is a case of chronic peritonitis due to the toxins of the dysentery bacilli. I was not able to follow this case up as the patient left the hospital soon after he was relieved by the tapping of the abdomen.

Urea stibamine in the treatment of kala-azar.—The drug has all the advantages over the antimony tartrates of sodium and potassium claimed for it except the claim for cure in one course of four injections. Perhaps I have not tried the drug sufficiently long to prove it. The question of cost is against its being freely used in a hospital. If the drug could really cure a patient in one course of four injections as claimed by its adherents, I should think it would be a decided advantage in spite of the costs as there would be a great saving in regard to the hospital stoppages."

The report of the 1st Surgeon, Lieut-Col. E. W. C. Bradfield, M.S., I.M.S., included an interesting analysis of cases of diseases of the stomach and duodenum operated upon during the last year.

"The fact that 530 patients suffering from ulceration of the stomach or duodenum were operated upon during the past three years by six surgeons with a total mortality of 11.5 per cent. in all cases is evidence that these diseases are very prevalent in South India. The statis-

tics of my own wards for the past year are as follows:—

inability to take any precautions about their diet would probably return with jejunal ulceration. Three patients

Diagnosis.	Number of patients.	Nature of operation.	Number.	Deaths.	Mortality per cent.
Duodenal ulcer	86	Gastroenterostomy	86	7	7.8%
Gastric ulcer	19	Do.	16	0	0
Cancer of stomach	5	Gastrectomy	3	1	25
Cancer of duodenum	1	Gastroenterostomy	4	0	0
Obstruction of duodenum	1	Cholecystenterostomy	1	0	0
Jejunal ulcer	3	Duodeno-jejunostomy	1	0	0
		Excision of ulcer	1	0	0
		Gastroenterostomy	1	0	0

Duodenal Ulcer.—The collected records of the above 86 cases of duodenal ulcer show that:—

1. The average age was 33, the oldest being 60, while two patients were only 18.

2. The average weight of these patients was 92 lbs. while five adults weighed under 65 lbs.

3. The average duration of symptoms was four years, the longest being 15 years and the shortest two months.

4. The appendix was inflamed in 21 patients and contained thread-worms in 40 (50 per cent.).

5. A second ulcer was present in 7 patients. Of these, five were on the lesser curvature of the stomach, one involved the pylorus, and one the duodenum.

6. One patient had a gall-stone with chronic cholecystitis and the operation successfully performed included cholecystectomy as well as a gastro-enterostomy.

The results of operation have been satisfactory considering the very feeble condition of many of these patients, especially those with advanced stenosis.

The causes of death in the 7 cases recorded have been as follows:—

(1) Shock. Three patients with severe stenosis, and poor operative risk.

(2) Pneumonia. One patient who died 18 days after operation with symptoms of pneumonia and gangrene of the lung; no post-mortem was allowed.

(3) Hæmorrhage. At operation early cirrhosis of the liver was noted. The patient had a fatal hæmatemesis on the 18th day after the operation. No post-mortem was allowed.

(4) Sepsis. A very mild sepsis which caused adhesions between the ileum and the scar of the anterior abdominal wall. The patient developed symptoms of intestinal obstruction on the 20th day but unfortunately refused any operative relief until he was in *extremis*.

(5) Hæmorrhage. This patient died 2 hours after operation with symptoms of collapse. Post-mortem; a small hæmorrhage was found in the abdomen due to a faulty ligature. The bleeding was not severe and his poor general condition and inability to stand any further shock largely accounted for the fatal results.

I believe that the universal use of the 'Fowler position' after these operations, by causing anæmia of the brain, may sometimes be partly responsible for disaster. Shock is really a poor explanation for a death occurring 36 hours after operation and where general emaciation, degenerate heart muscle and small atrophied liver are the only post-mortem findings. Recent work has suggested that the sitting up posture may be responsible for an acute dilatation of the stomach where the pull of the intestines and mesentery causes the superior mesenteric vessels to obstruct the last part of the duodenum. One of our patients who developed acute dilatation of the stomach six days after operation certainly seemed to suggest the correctness of this theory. Washing out the stomach had produced no relief and we decided to raise the foot of the bed as high as possible and to turn the patient over with face down. The result was extraordinary, for all the symptoms passed away within about five hours and did not recur.

In last year's report, it was predicted that a number of patients on account of their economic condition and

were seen during the year, two operated on elsewhere and one of our own patients. (Patients frequently resort to other surgeons when their symptoms recur). For one patient admitted in a moribund condition with acute dilatation of the stomach, nothing could be done. In another patient adhesions around a stenosed jejunal ulcer were so numerous that the ulcer itself could not be dealt with but a second gastro-enterostomy produced relief and improvement in the general condition. In the third patient excision of a jejunal ulcer which had perforated the transverse colon was necessary and has apparently produced a cure. In both patients operated upon, the original duodenal ulcer was completely healed, though stenosis remained but it did not appear feasible to undo the anastomosis.

Gastric Ulcer.—The percentage of ulcers involving the stomach is rather larger than usual. The mortality from partial gastrectomy is very high and it is not now attempted except in selected cases. One death from this operation was due to shock and the other, an emaciated patient, aged 30, died from volvulus of the intestines, which developed three days after the operation and when the patient's condition was too critical to allow of any relief. Two patients were noted as being probably cancerous and were too ill for more than a rapid short circuiting to be done, but left hospital with relief of all symptoms. One patient had a peculiar leather-bottle condition of the stomach. He also was too ill for more than a gastro-enterostomy but improved very rapidly after operation, a happy result probably aided by a course of anti-syphilitic treatment suggested by a strongly positive Wassermann reaction.

Cancer of stomach.—Five patients, one of whom was too ill to stand any operation. In three of these the diagnosis was proved by microscopic examination of enlarged glands.

Cancer of duodenum.—This patient was admitted to hospital with intense jaundice and a dilated gall-bladder. Exploration found a cauliflower growth at the ampulla of Vater and temporary relief of symptoms was obtained by a cholecystenterostomy.

Obstructed duodenum.—This patient had suffered from symptoms of dyspepsia for six years. Operation disclosed dilatation of the first part of the duodenum caused by enlarged, possibly tuberculous glands, at the root of the mesentery. Duodeno-jejunostomy produced complete relief.

TUBERCULOUS ABDOMEN.

Tuberculosis amongst cattle appears to be unknown in the Madras Presidency and although no bacteriological investigations have been made, it is more than probable that this absence of bovine tuberculosis influences the incidence and character of the disease in South India. Tuberculous diseases of bone and joints, though not so commonly seen as in European hospitals, pursue a much more intractable course and appear to be less amenable to non-operative forms of treatment. The economic problems of this country and the ignorance of people of the hospital class, are contributory factors, but multiple lesions appear to be more common and the surgical forms are more frequently complicated by the presence of lesions in the lungs.

In 1924, 205 patients were admitted to the General Hospital, Madras, for surgical forms of tuberculosis, or 2.1 per cent. of the total admissions. The sites of the disease were as follows:—

Abdomen	95
Lymphatic glands	39
Bones	35
Joints	28
Abscess (not classified)	3
Skin	2
Testis	1
Kidney	1
Larynx	1
Total	205

Abdominal tuberculosis (including enteritis 20) accounted for 95 of these patients or 0.97 per cent. of the total admissions to the hospital, a very much higher percentage than is found in European general hospitals for all ages, and a figure approximately to that of children's hospitals, where it generally averages from 0.05 to 2 per cent. of the total admissions.

The admissions to medical and surgical wards were as follows:—

Tuberculous peritonitis	55
Tuberculous enteritis	20
Tuberculous cæcum	20

I have endeavoured to estimate the value of surgical treatment in what is undoubtedly a common form of tuberculosis in South India by a study of the First Surgeon's operation registers of the General Hospital for the past six years. These researches only show the type of disease found and the immediate results of operation. The difficulty of tracing Indian patients is very great but some idea of the ultimate results can be obtained from my personal notes. Most of our enquiries remained unanswered. One patient, who replied some months after the notices had been sent, had been so alarmed at the receipt of a letter that he at once buried it and it was only opened when he considered a safe period had elapsed.

The results of operation have been as follows:—

	Total.	Mortality.
Tuberculous peritonitis	43	14*
Tuberculous cæcum		
Excision of cæcum	14	2
Ileocolostomy	6	0
Simple laparotomy	7	0
Cæcostomy	1	1

* 3 died within three months of leaving hospital.

I. TUBERCULOUS PERITONITIS.

1. *Ascitic Variety.*—Of three patients operated upon, one with extensive involvement in the pelvis died after two months. This variety in its true form is comparatively rare and not enough cases have been recorded to test the value of simple laparotomy, the usual treatment advocated. Operation when fluid in the abdomen has been diagnosed has generally revealed the presence of the numerous adhesions which characterise the next type and in which the results of operative interference are very poor.

2. *Fibrous and Adhesive Variety.*—Of 40 patients submitted to operation 11 died, a mortality of 27.5 per cent. Many of these patients were operated upon for acute complications. Perforation of tuberculous ulcers with resulting acute peritonitis accounts for four, with four deaths; intestinal obstruction 5, with 3 deaths; infected tuberculous abscess 4, with 3 deaths. In 6 patients enlarged tuberculous glands were a prominent feature and in two of these infection had taken place in a chronic abscess with fatal results.

The average age of the majority of these patients (22 out of 39) was between 20 and 30 years. In typical cases diagnosis is not difficult. Abdominal pain, sometimes with definite relation to taking food, and fever

are complained of, while a doughy, distended abdomen often with evidence of free fluid in the peritoneal cavity, sometimes with a tumour mass or with visible peristalsis due to chronic obstruction are signs which cannot be mistaken. In the early stages chronic dyspepsia resistant to treatment, sometimes with tenderness in the right abdomen may render diagnosis difficult, but the pain never has the relapsing character of a duodenal or gastric ulcer. A tumour mass may call for an exploratory laparotomy but the results immediate and remote with these patients are very poor.

II. TUBERCULOUS DISEASE OF THE CÆCUM.

Ileo-cæcal tuberculosis was described by Hartman (to whom we owe the best description of this disease) as a form of tuberculosis very amenable to operative interference and more common than is generally recognized. A record of 20 cases in one year is evidence that the disease is very common in South India, though it is probable that many of the patients who were not submitted to operation, were really extensive examples of fibrous peritonitis. The disease occurs in two forms, in both of which a mass is found in the right iliac fossa. The entero-peritoneal form is an ulcerative caseous tuberculosis not confined to the cæcum but attacking also the ileum and the appendix. The ileo-cæcal region becomes lost in a mass of adhesions, among which caseating cavities form and in the later stages pyo-stercoral fistulae are found. This variety may simulate an appendicitis and the signs are those of an enteritis, never of obstruction. The lungs are frequently involved. Actinomycosis has never been seen in South India but in other countries may produce similar symptoms. The hyper-plastic variety simulates a neoplasm in the right iliac fossa and after a very vague insidious onset, the symptoms are those of a chronic intestinal obstruction. Tuberculous foci are scanty, surrounded by a dense fibrous tissue mass and associated with other purely inflammatory lesions, as for example, dense sclero-adipose-thickening and the production of numerous polypi and vegetations in the mucous membrane. The disease in this variety is confined until late to the cæcum, the walls of which are converted into a hard, rigid mass associated often with very extreme stenosis. Ulcers are sometimes found in the ileum and a similar hyper-plastic condition may occur in other parts of the large intestine. The lymphatic glands are often markedly infected.

The disease, as we have seen it at operation, has had the characters of the hyper-plastic variety rather than of the ulcerating caseous entero-peritoneal form. There are a number of specimens of the disease preserved in the Medical College Museum, all of which show massive fibrous formation in the walls of the cæcum. Of 28 patients whose operations were recorded, six were too ill or too extensive to allow of more than an exploratory laparotomy and cannot be classified. Five appeared to have been entero-peritoneal in character, 17 were hyper-plastic, one of which involved the sigmoid flexure. An interesting point about all these patients is that the ages noted were from 25 to 35 except four, aged 43, 45, 9 and 17. This agrees with Hartman's description that the disease presents its maximum frequency between the ages of 20 and 40.

My own records suggest that the hyper-plastic variety is not so entirely confined to the cæcum as the original description would suggest and this is borne out by the brief notes of the other surgeons. The reason of course may be that our patients are seen at a later stage than in a more educated European community. In six patients the disease was entirely confined to the cæcum, in two there were scattered ulcers on the lower part of the ileum, and in two, in addition to ulcers on the ileum, there were a number of scattered miliary tubercles over the peritoneum of the small intestine. In the patient on whom a cæcostomy was done the tuberculous mass was entirely confined to the splenic flexure but on account of his poor general condition and the presence of a sub-acute obstruction, no radical treatment could be attempted. In only three of these eleven patients

was there obvious disease in the lungs. Col. Niblock reported one patient, entero-peritoneal variety, on whom a lateral anastomosis was completed with complete success. A further operation was performed by him on this patient some months after the original, and the tuberculous mass was found to be entirely healed, no evidence of tubercle remained.

Of my eleven patients, one cæcostomy died five days after the operation, another patient with extensive disease in the lungs died on the 5th day after an ileocolostomy. Of the remaining nine patients (excision of cæcum) seven left hospital with apparently an excellent result. All the nine patients were discharged from the hospital and we have been able to trace the after-history of five of them up to two years.

(1) Male, aged 35, tuberculous cæcum, entero-peritoneal. There were several scattered ulcers on the ileum and miliary tuberculous nodules on the peritoneum. Tuberculous infection present in both lungs. The chief signs were pain in the abdomen, chronic diarrhoea and a tumour in the right iliac fossa. *Operation:* excision of cæcum with lateral anastomosis. The patient developed a faecal fistula at the site of operation and was discharged with this still not healed. He died six months after operation as a result of general tuberculosis.

(2) Female, aged 38, had been treated at a sanatorium for tuberculosis of the lung with improvement. History of a hard, fixed mass in the right iliac fossa for several years. Lately she has been subject to attacks of pain, which commence 1½ hours after food and are relieved by vomiting.

Operation: excision of cæcum with lateral anastomosis of ileum to transverse colon. Hyper-plastic disease of the cæcum but the coil of the ileum in the pelvis was studded with tubercles and matted together. Pathologist's report says that the ileocaecal valve was stenosed to almost complete obstruction by hyper-plastic tuberculosis. Following the operation she had a broncho-pneumonia which caused considerable anxiety for some time but eventually cleared. A faecal fistula developed at the wound but this healed with careful dressing two months after the operation. This patient is still at the sanatorium, eighteen months after the operation. Her general condition is slowly improving but she still gets fever after over-exertion.

(3) Remaining cases: girl aged 20, man aged 45, and girl aged 18, with typical hyper-plastic tuberculosis. Two and a half, two, and one year after the operation, they each appear to be in excellent health and free from tuberculosis.

The treatment of these forms of ileocaecal tuberculosis should be surgical, and if seen at a reasonably early period, the results will be very satisfactory and the dangers of the patient developing further tuberculous lesions remote. Simple laparotomy is of course useless, and short circuiting, or ileocolostomy should be reserved for advanced degrees of the disease or for the entero-peritoneal variety, which presents many difficulties both on account of the adhesions in the abdomen, and the often extensive distributions of the tuberculous infection. Excision of the cæcum including any involved area of ileum or ascending colon is not a very difficult operation, and the divided ileum is joined either to the transverse colon or to the sigmoid loop. The average reported mortality from the operation varies from 12 to 25 per cent. and though we have had no mortality in our last seven operations, two of these patients developed very alarming symptoms of severe toxæmia and were acutely ill for 48 hours. Handling of the tuberculous mass probably accounted for this condition but recovery from the operation was otherwise very rapid and satisfactory. A two-stage operation does not appear to be necessary except for very feeble patients. Two of our patients developed faecal fistulae, an accident I attribute partly to the drainage employed, and which I now endeavour if possible to avoid.

Two other unusual forms of abdominal tuberculosis in the period under review are worthy of note here.

One patient with typical tuberculous ulcers in the upper part of the jejunum was operated upon under the mistaken diagnosis of duodenal ulcer. Another patient with symptoms mainly gastric was found to have a complete fibrous structure at the ileo-cæcal valve. No evidence of tuberculosis could be found and the patient made a complete recovery after excision of the cæcum. We have not been able to trace the further history of this patient but the condition, as in two similar cases reported by Hartman, may have been tuberculous in origin."

ANNUAL REPORT ON THE WORKING OF THE HOSPITALS, DISPENSARIES, JAIL HOSPITALS, AND THE REGISTRATION OF VITAL STATISTICS IN THE CENTRAL INDIA AGENCY FOR THE YEAR 1923 AND ON VACCINATION FOR 1923-24. CALCUTTA: GOVT. OF INDIA CENTRAL PUBLICATION BRANCH, 1925. PRICE RS. 6.

DURING the year one travelling dispensary was opened by the Bhopal State. Four other dispensaries have been opened in various States but as these do not appear in the statistical returns from their respective Durbars they are not included in this report. Thus the total number of hospitals and dispensaries in Central India, excluding those for which the returns have not been received, was 214 compared with 215 in the previous year; the apparent decrease is due to the fact that two other dispensaries that existed during the year were not included in the returns.

The number of patients treated during the year was 1,654,509 as against 1,579,696 of the previous year, i.e., an increase of 74,813. The in-patients number 20,035 compared with 20,826 of the previous year. The number of operations performed was 63,368 as compared with 59,554 of the previous year.

The prevailing diseases were the same as during the previous year; numbers recorded under the six principal headings were:—

Malaria	295,000
Eye diseases	263,518
Skin diseases	164,393
Disorders of the digestive system	139,656
Ulcers	115,559
Rheumatic affections	44,709

Both syphilis and tuberculosis showed a slight increase again this year.

Vaccination.—During the year 1923-24 the number of vaccinations done was 141,721 as against 146,396 done in the preceding twelve months. Of these 140,229 were primary and 1,492 were secondary. One hundred and sixty-five vaccinators were employed during the year. The lymph was obtained from various sources. The lymph prepared at Manpur was distributed as before at a comparatively small cost; it gave good results.

Epidemics.—The Central India Agency remained entirely free from cholera during the year 1922 but during 1923 there were 77 cases with 62 deaths reported. The largest number of cases occurred in April; 48 out of the 62 deaths occurred during this month.

On the other hand the plague incidence was reduced; during the year 584 cases were reported compared with 1,019 of the previous year. The death rate was, however, high, 510 deaths occurring during the year. The highest incidence occurred in March and April; all the deaths that occurred in Bundelkhand Agency occurred during this month.

Small-pox accounted for 62 deaths out of a total of 547 attacked.

Lunatics and lepers.—There has been an increasing demand for accommodation in the lunatic asylum in

Indore City but as this was limited by want of space the asylum has been moved to Banganga where a more suitable house was available.

There are three leper asylums; the average number of inmates in these three asylums is a total of 66.

Correspondence.

BACK NUMBERS OF THE INDIAN MEDICAL GAZETTE.

The Secretary of the Office International d'Hygiene Publique, 195 Boulevard St. German, (VIIe Arr.), Paris, has written to us asking whether any subscriber can supply him with the *Indian Medical Gazette* from August, 1920 to the end of 1925 inclusive.—EDITOR, I.M.G.

"THE DARLING PRIZE."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the events recorded in the enclosed copy of a note which appeared in the issue of *Nature* for 28th November 1925, I have been asked by the President of the Health Committee of the League of Nations to bring to the notice of British friends and fellow workers of the late Dr. S. T. Darling that a list has now been opened at Geneva for contributions to the capital fund to found "The Darling Prize." As it is probable that a large number of workers on subjects connected with tropical medicine and hygiene may wish to be associated with the Health Committee's plan for honouring Dr. Darling's memory, I would suggest that individual subscriptions should not exceed one guinea. Any one wishing to contribute should please forward his subscription to the Medical Director, Health Section, League of Nations, Geneva, who will acknowledge all sums received. Detailed regulations concerning the award of the Darling Prize will be drawn up as soon as the Health Committee can form an estimate of the sum likely to be available. All decisions on this subject will be at once communicated to subscribers. You will see that the Darling Prize is being treated apart from the proposed memorial to the late Dr. Lothian ("The Lothian Scholarship"). The latter memorial is being provided, not by private subscription, but by the organisation of the League of Nations of which he was a permanent member.—Yours, etc.,

G. S. BUCHANAN,

Senior Medical Officer,

Ministry of Health and British Member of
the Health Committee of the League
of Nations.

WHITEHALL, LONDON, S.W.1.
18th January 1926.

The following is the note from *Nature*:—

THE DARLING AND LOTHIAN FOUNDATIONS FOR RESEARCH IN MALARIA.

SOME months ago we had to record (*Nature*, May 27th, p. 845), with much regret, the deaths in a motor-car accident, near Beirut in Syria, of Dr. S. T. Darling (United States of America), Dr. N. V. C. Lothian (England), and Mlle. Besson (France), members of the Malaria Commission of the League of Nations who, with Prof. Nocht (Hamburg), Swellengrebel (Amsterdam), Ottolenghi (Italy), Anigstein (Poland) and Colonel James (England), were undertaking a tour of investigation in Palestine, Syria, and part of Turkish Asia Minor. In the recently published report on the work of the fifth session of the League's Health Committee, held at Geneva on October 8th to 14th, it is

announced that the Committee, wishing to honour and perpetuate the memory of Dr. Darling and Dr. Lothian, has decided:—

(1) To collect by private subscription a capital fund, the interest on which will be expended on a prize to be awarded periodically. This will be known as "The Darling Prize."

(2) The Prize (a medal or other reward) will be awarded by the Malaria Commission of the League of Nations to a scientific worker who, in its opinion, has carried out recent distinguished research on a subject connected with malaria which comes within the general scope of the Commission's investigations.

(3) To devote a portion of the credits provided for in the budget of the Health Organisation for the encouragement of malariological study to the establishment of a periodical scholarship to be known as "The Lothian Scholarship." This scholarship will be awarded by the Malaria Commission to a selected candidate whose course of study should be in conformity with the general programme of the Malaria Commission.

In our issue of August 8th, p. 216, we printed the substance of an appreciation, from the pen of Prof. R. W. Hegner, of the life and work of Dr. Darling. In the Malaria Commission's report of the Palestine tour, which preceded the journey to Syria on which the tragic accident occurred, it is said that the Commission had frequent occasion for congratulation that Dr. Darling had found it possible to be one of the party. "His previous experience of malarial epidemiology and anti-malarial operations in many countries was unrivalled. He appreciated very clearly the particular aspect of the subject with which the Commission's mandate is chiefly concerned, and his observations during the tour constantly proved that he was at the zenith of his powers as an expert adviser on antimalarial work."

Dr. Lothian joined the Secretariat of the Health Section of the League in May 1923, after a career of considerable achievement in the Royal Army Medical Corps. He had specialised in hygiene, and some of the scientific papers which he published during his army service were of outstanding merit and practical usefulness, notably his "Historical inquiry into the load carried by the soldier of various periods," in which he showed that a soldier should not be required to carry more than 33 per cent. of his own weight; the load of a mule is 32 per cent. and a horse 28 per cent., and to require a soldier to carry more than 33 per cent. is to destroy his marching power and capacity for battle."

Dr. Lothian, during his two years' service with the League, travelled in many countries and came into close contact with administrators and public health officers of many nationalities. He accompanied and guided the "interchange courses" of foreign public health and medical officers which, in collaboration with the Rockefeller Foundation, now form a regular item in the programme of the Health Organisation at Geneva. He was secretary to the League's Malaria Commission, and in the report of the Commission's tour of investigation through eastern Europe and Russia, which was published last year, the chapter entitled "Summarised Impressions of the Tour" was wholly drafted by him. It is a sufficient illustration of his expert knowledge of the subject and of the industry which characterised all his work. His high sense of duty and his attractive personality gained him the highest regard and respect wherever he went, and the shock of his death was the greater because he was in the exuberant vigour of youthful manhood, looking forward with enthusiasm to the highest and best that life holds in store.

B. COLI INFECTION IN THE PUERPERIUM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was very interested to read Dr. Buchia's article in the February number of the *Indian Medical*

Gazette, on page 73. The question I asked in the June number of 1925 was:—Is there a puerperal fever in which the bladder and urinary passages alone are infected, the uterus being normal and sterile? I believe I have seen two such cases in India. If the answer is, yes, then it is clearly a contingency for which obstetricians should watch, as it is probably both preventable and curable.—Yours, etc.,

G. T. WRENCH, M.D., B.S. (Lond.).

VICTORIA ROAD,
KARACHI,
20th February 1926.

GLYCOSURIA IN LEPROSY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I read with interest the statement of P. S. Srinivasan in regard to glycosuria in leprosy. In my last year's work among lepers of all types I have not found it more common than among an equal number of ordinary dispensary patients, and then in all probability it was due to a coexisting diabetes mellitus. However it would seem possible that there could be a leprosy diabetes due to infiltration of the pancreas.

The results obtained by Dr. Srinivasan were obtained with Fehling's solution which is remarkably unreliable as a test for sugar, but like many other unreliable things it takes a long while before they are no longer used. Fehling's solution is not stable and besides a reaction with glucose it also reacts with conjugate glycuronates, uric acid, nucleoprotein, homogentisic acid, phosphates of the alkaline earths and with creatinine. Thus when positive reactions are obtained it is difficult to know to what they are due. The strong alkalinity of Fehling's solution has a tendency to destroy some sugar which if present in small amount may thus escape detection entirely.

The solution which we use and which we have introduced into Chandkuri Asylum is Benedict's. It detects smaller amounts of glucose, as little as 0.015 to 0.02 per cent., and it does not deteriorate on long standing. There is no troublesome mixing of solutions prior to use, it is always ready.

The test is very simple and the solution is made up as follows:—

Copper Sulphate	..	17.3 gms.
Sodium citrate	..	173. gms.
Sodium carbonate (anhydrous)	..	100 gms.
Distilled water	..	to 1000 mls.

The citrate and carbonate are dissolved by heat in 600 c.c. of water, filtered if necessary. The copper sulphate is dissolved in 100 c.c. water and made up to 150 c.c. The first solution is then placed in a jar or beaker and the copper solution slowly added while stirring constantly. The solution is now ready for use.

To apply the test:—

Five c.c. of Benedict's solution are placed in a test tube and to it are added exactly eight drops of the urine to be tested. Boil for one or two minutes and cool spontaneously. If glucose is present the solution will be filled with a red, yellow or green precipitate depending on the amount present. If none is present the solution remains clear with color unchanged. When one gets a positive test with this test he is sure that it is due to glucose.

It would be interesting if Dr. Srinivasan would check his findings by using Benedict's solution in place of Fehling's.—Yours, etc.,

MILTON C. LANG, M.D.,
Medical Superintendent,
Chandkuri Leper Asylum.

THE GENERAL PRACTITIONER AND MEDICAL RESEARCH.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Within recent years the idea is gaining ground amongst the general practitioners in India especially (with a few exceptions) that medical research is the special prerogative of a few isolated laboratory workers; and that the "g. p." has absolutely nothing to do with it. Some of them even go a step further and say that it would be presumptuous on the part of a general practitioner to talk of medical research. It is this idea, I think, that is mainly responsible for the present secession of general practitioners from medical research. It is a matter for regret that none of such medical men have ever considered the consequences of their actions. It is to correct this prevalent wrong notion that the following few lines are penned.

True it is that certain kinds of research call for the highly skilled specialist but the general practitioner can do a lot with his observant eyes. I think that he has to bear the lion's share of the burden. The specialist can work only through a particular line of action but multifarious are the lines of action for the general practitioner. He has greater opportunities for research than an isolated laboratory worker who depends for his clinical material upon his brothers, the "g. ps." It is only after they have by their accurate clinical observations separated a disease as a distinct entity from a host of other homologues that the laboratory worker begins to apply his weapons of refining and perfects the finding. Without the material how could the laboratory worker work? To put it in another way the general practitioner has to take the initiative, find out something new by his clinical observations and arrive at certain conclusions based upon all the observed facts; then his "specialist" brother comes to his assistance and with his delicate appliances investigates and either corroborates the findings of the clinician or proves that they require to be corrected or modified by further observations. Thus it is seen that the specialist and the general practitioner have to work in collaboration with each other, the one supplementing the other.

To give an instance of how a general practitioner can assist his brother "specialist":—he can observe the incidence of a particular disease in a particular region, or season or climate, its occurrence in relation to the environment—housing, food, water, air, or social conditions of life, its prevalence in a particular community or class, the different clinical manifestations of the same disease in different individuals at the same or different times or in different regions, or the constancy in the clinical manifestations of the disease whichever region or climate it occurs in, and can give suggestions as to the possibility of its being an infection, or an intoxication or an aberration of the metabolism, as may reasonably be inferred from the observed clinical data; and also suggestions as to the possibility of a particular channel of transmission, and the avenue which the specialist has to explore with his arms and ammunitions of laboratory apparatus and reagents.

The practitioner cannot even stop here. He has to follow his brother the "specialist" throughout his journey and cheer him up when he has to ascend the hills that may be on the way, or even suggest to him an alternative route, and finally when the formidable enemy has been caught to put the results of the hard labours of the specialist to the crucial test of clinical application and give his verdict.

He has to watch with patient eyes and try to assist his brother the specialist in the laboratory with fresher materials to work with. The general practitioner can no longer afford to shut his eyes and keep himself aloof from his brother the specialist. He has to come forward to bear his legitimate share of the burden.

Can the general practitioner himself take the initiative in research? Yes,—he can,—with wonderful results—

BAITALPUR, C. P.
VIA BHATAPARA, B. N. RY.
2nd March 1926.

if properly carried out. As an instance of what the observant eyes of the general practitioner can accomplish, I may point out "the magnificent work on heart disease" of the late Sir James Mackenzie, to quote Colonel Megaw. The field of the laboratory worker is limited, whereas that of the general practitioner is very wide.

The great father of medicine, Hippocrates had no microscope nor electric centrifuge, but marvellously enough he has bequeathed to us a wonderfully accurate clinical description of the diseases that decimate mankind; and he was able to separate and identify distinctly very closely allied diseases; for example, the three types of malarial fevers were clearly identified by him and the group of malarial fevers separated from a host of other similar fevers at a time when he had not even the advantage of such common clinical appliances as we now possess. This bears eloquent testimony to what can be accomplished by the observant eyes of the general practitioner. Many more instances could be cited, but one is as good as many. Thus it is clearly seen that the "g. p." has played a very prominent part in the past history of medical research.

In countries other than India the "g. p.'s" continue to follow in the footsteps of their glorious predecessors. Will the "g. p." in India now at least try to shake off his present indifference and ignorant prejudice towards research and come forward to associate himself in increasing degrees with his brother "specialist" who has been manfully waging war single-handed with the formidable opponent disease?

Brother "g. p.'s", please consider well and come forward.—Yours, etc.,

G. R. RAO.

CALCUTTA,
Dated 19th January 1926.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Colonel A. N. Fleming, D.S.O., M.B., F.R.C.S., I.M.S., to be Honorary Surgeon to the King, Indian Military Forces, *vice* Colonel P. Dee, M.B., I.M.S., (retired). 9th June 1925.

The services of Colonel R. A. Needham, C.I.E., D.S.O., I.M.S., Officer on special duty with the Railway Department (Railway Board) are replaced at the disposal of the Department of Education, Health and Lands, with effect from the afternoon of the 27th March 1926.

Major G. M. Millar, O.B.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Residency Surgeon, Mewar, with effect from the 2nd March 1926.

The services of Major V. Mahadevan, F.R.C.S.E., I.M.S., are placed permanently at the disposal of the Government of Madras, with effect from the 4th September 1925.

Major H. W. Acton, I.M.S., Professor of Tropical Pathology and Bacteriology, School of Tropical Medicine and Hygiene, Calcutta, is appointed to act, in addition to his own duties, as Director of the said institution, *vice* Lieutenant-Colonel J. W. D. Megaw, C.I.E., M.B., I.M.S., V.H.S., granted leave.

Major W. O. Walker, F.R.C.S.E., I.M.S., Civil Surgeon of Serampore, is appointed to act, in addition to his own duties, as Civil Surgeon of Hooghly, during the absence, on leave, of Lieutenant-Colonel C. A. Godson, I.M.S.

On return from leave, Major C. R. O'Brien, M.B., I.M.S., Civil Surgeon, is posted to Dacca, *vice* Lieutenant-Colonel M. Mackelvie, C.I.E., M.B., F.R.C.S.E., I.M.S., granted leave.

Major J. D. Sandes, M.B., F.R.C.P.I., I.M.S., officiating Professor of Medicine, Medical College, Calcutta, and First Physician, College Hospital, is appointed to act as Principal of the said institution, with effect from the 16th April 1926, *vice* Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., M.B., F.R.C.S.E., I.M.S., granted leave.

The services of the undermentioned officers are placed permanently at the disposal of the Government of Burma, with effect from the dates shewn against their names:—

Captain H. Aung Khin, I.M.S., 2nd August 1922.

Major A. L. Sheppard, I.M.S., 22nd December 1922.

Captain L. S. Modi, I.M.S., Superintendent of the Buxar Central Jail, is appointed temporarily to be the Superintendent of the Bhagalpur Central Jail during the absence, on leave, of Captain U. J. Bourke, I.M.S., or until further orders.

LEAVE.

The Hon'ble Major-General Sir Charles MacWatt, Kt., C.I.E., K.H.S., I.M.S., Director-General, Indian Medical Service, is granted leave on average pay for six months with effect from the 1st April 1926.

Lieutenant-Colonel J. W. D. Megaw, C.I.E., M.B., I.M.S., V.H.S., Director, School of Tropical Medicine and Hygiene, Calcutta, is allowed leave on average pay for four months, under articles 81 (b) (i) and 82 (b) of the Fundamental Rules, with effect from the 15th July 1926.

Lieutenant-Colonel C. A. Godson, M.C., I.M.S., Civil Surgeon, Hooghly, is allowed leave on average pay for eight months, under article 81 (b) (i) of the Fundamental Rules, with effect from the 12th May 1926, or any subsequent date on which he may avail himself of the leave.

Lieutenant-Colonel M. Mackelvie, C.I.E., M.B., F.R.C.S.E., I.M.S., Civil Surgeon, Dacca, is allowed leave on average pay for eight months, under article 81 (b) (i) of the Fundamental Rules, with effect from the 15th May 1926, or from any subsequent date on which he may be relieved of his duties.

Major L. A. P. Anderson, I.M.S., Officiating Assistant Director, Central Research Institute, Kasauli, is granted leave on average pay for 8 months combined with leave on half average pay for 3 months and 10 days and study leave for 8 months and 20 days, with effect from the 5th April 1926, or such subsequent date as he may avail himself of the leave.

Captain G. Shanks, M.D., I.M.S., Professor of Pathology, Medical College, Calcutta, and Bacteriologist to the Government of Bengal, is allowed combined leave for one year, viz., leave on average pay for eight months under article 81 (b) (i) of the Fundamental Rules, and study leave for four months under rules 1, 2 and 6 of the Study Leave rules for the Indian Medical Service officers, with effect from the 22nd October 1926.

PROMOTIONS.

Majors to be Lieutenant-Colonels.

K. G. Gharpurey, D. C. V. FitzGerald, M.C., B. Higham, M.B., S. T. Crump, J. M. Skinner. —Dated 1st February 1926.

C. R. O'Brien, M.B. Dated 1st March 1926.

Captains to be Majors.

K. R. Rao, H. Chand, M.C., N. D. Puri, M.B., M. Das, M.C., M.B., J. B. Vaidya, J. M. R. Hennessy, C. H. N. Bakar, M.C. —Dated 31st January 1926.

M. L. Treston, F.R.C.S., A. Chand, M.B., R. Lee, M.B., C. de C. Martin. —Dated 1st February 1926.

RETIREMENTS.

The King has approved the retirement from service of Lieutenant-Colonel C. M. Mathew, I.M.S., from 2nd November 1920.

The King has approved the retirement from service of the following officers, with effect from the dates specified:—

Lieutenant-Colonel R. F. Standage, C.I.E., F.R.C.S., I.M.S. 28th January 1926.

Lieutenant-Colonel W. Gillitt, C.I.E., M.D., I.M.S. 16th February 1926.

NOTES.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

(Division of Tropical Medicine and Hygiene.)

EXAMINATION RESULT. 79TH SESSION. OCTOBER 1925—FEBRUARY 1926.

Passed with Distinction:—

R. M. Morris—Winner of "Duncan" Medal.
W. A. Young.
H. L. Batra.

T. Y. Li.
T. P. Noble.
A. K. El Shurbagi.

HÆMOSTYL, ROUSSEL.

An interesting new preparation is Hæmostyl, Roussel. This is an activated horse serum for the treatment of hæmorrhagic states and of anæmias of all grades. In 1906 Carnot and Deflandre discovered that in a healthy vigorous animal blood-letting induces an intense tissue reaction followed by a marked blood regeneration; further that the tissue reaction is due to an active substance present in the serum, which is destroyed at 55°C. This substance they termed "hæmopoietine," and if a serum rich in this substance be introduced into another animal deficient in blood cells, a very rapid hæmopoietic reaction occurs.

In preparing Hæmostyl, Roussel, young healthy horses are first selected, and a first copious bleeding resorted to. After this the animal reacts and the blood is drawn off at the moment when the hæmopoietic reaction is most intense, as measured by blood counts. The serum

is sterilised by five heatings to 55°C. It is this serum which constitutes Hæmostyl.

This serum is indicated in all hæmorrhagic states, such as post-partum hæmorrhage; secondly, in anæmias of all-classes; thirdly, in chronic infectious diseases associated with anæmia, such as relapsing malaria, sprue, tuberculosis and the like. It is put up in ampoules for subcutaneous administration, or for rectal injection; as Hæmostyl-Syrup for oral administration, and as desiccated Hæmostyl tablets for oral administration. Published reports bear witness to its value in the anæmia of tuberculosis, in hæmoptysis, as a local dressing in burns and ulcers, and in hæmatemesis. The manufacturers especially insist on its value by oral administration. They are J. B. Fialip, 21 Rue d'Aumale, Paris.

"PANCREPATINE, A. F. D."

An interesting preparation recently put upon the market by the Anglo-French Drug Co. (Eastern), P. O. Box 460, Yusuf Building, Church Gate Street, Bombay is "Pancrepatine." This is a combination of an extract from the pancreas with a hepatic extract, put up in gluten-coated globules for oral administration, and has been highly spoken of by writers in the French medical journals. Whereas insulin is a drug the use of which in diabetes must necessarily be confined to cases under strict medical supervision, it is claimed that Pancrepatine can be taken by the patient without special supervision. For an adult diabetic the course advocated is to begin with 6 globules taken daily with meals, and increase to 12, at which dosage 4 capsules are taken t.d.s. with food until the urine becomes sugar-free. The diet must be reduced to a total carbohydrate intake of 70 to 80 grammes, but can subsequently be gradually increased.

A second new preparation by the same firm is their "Benzo-bismuth", referred to on p. 214 of this issue. In general there now appears to be a tendency to return to the injection of soluble, rather than of insoluble, bismuth compounds in the treatment of syphilis and frambæsia. It is claimed for Benzo-bismuth that it is very stable, it contains 20 per cent. of bismuth, there is no fear of its being retained in the tissues as with insoluble preparations, therapeutic results are very good, whilst administration is very simple and free from all risks.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

MEDICAL ASPECTS OF LIFE INSURANCE IN INDIA, WITH SPECIAL REFERENCE TO CALCUTTA.

By EDWARD HOUSEMAN, M.A., M.D., B.C.,
D.P.H. (Cantab.)

Chief Medical Officer in India to The Commercial Union Assurance Co., and The Phoenix Assurance Co.

IN writing on life insurance in India, one finds that there is a great scarcity of books of reference and also that the only vital statistics of any real value are those which relate to the Presidency towns.

In the districts a very small percentage of fatal illnesses are seen and diagnosed by qualified medical men and the mortality statistics for the general civil population are usually returned by uneducated village watchmen, so they are of little value.

For these reasons my investigations have been confined principally to Calcutta, which city, though no longer the official capital of India, may I think, still claim to be the commercial capital. Most of the insurance companies, which operate in India have their head offices in Calcutta, and consequently the major portion of the insurance work done in the peninsula is referred to this city.

The duties of an insurance medical officer in India are very similar to those of his colleague in Europe, but I think the Eastern examiner has the greater difficulty in presenting an accurate report to his company.

Proposers in all parts of the world when asked to record their past illnesses have short memories and in this respect the oriental may be regarded as an expert, so much so that it is unusual for an examiner to find any proposer, no matter what his age may be, to have suffered from any illness more serious than a slight attack of fever. In consequence the examiner usually has to conduct an elaborate cross-examination before he can hope to approach the truth, and in doing so he speedily learns to pay more attention to the way answers are given than to what the actual answers are.

Some of this inaccuracy is often unintentional, but in many cases it is deliberate and not infrequently proposers are coached by their agents before they come up for examination, so that they shall not make statements which may adversely influence the examiner. In these days of keen competition to secure new insurances, proposers, when rejected by one office, are often persuaded to try and effect an insurance with a second one, in which they are sometimes successful and manage to get themselves accepted at ordinary rates by the second office.

From this it will be seen that the standard required by different companies varies consider-

ably, many seem to be rather too severe and this applies more especially to some of the Home companies, who are rather afraid of Indian risks and often do not readily accept the opinion of either their local representatives or their medical examiners. On the other hand some companies are very easily satisfied and are content with a medical examination which is of little value. On one occasion recently a friend of mine wished to take out a policy with a company having a large Indian business. He is a man about six feet and many stones over the maximum weight for his height. The examiner looked at him and promptly said such a big man must be a first class life, so my friend was accepted as a first class life after a very superficial examination.

In another case it was discovered in the office of a large company that the weighing machine had been out of order for a considerable period, during which time all heights and weights taken had been approximate ones.

Often it is difficult for companies to find competent and reliable examiners, this does not apply so much to the Presidency towns but it is a very real difficulty in up-country stations. I was recently asked to give an opinion upon some twenty cases in which one examiner had recorded the pulse-rate at 72 in each case.

In Bengal, where most of my work has been done, the majority of Indian proposers are chiefly of the clerical and professional classes amongst whom it is exceptional to find any following the more dangerous trades. The indigenous population do not take kindly to hard work, they prefer to confine themselves more to clerical and political work, with the result that very few of the mechanical trades are in their hands, they are being done either by Mahomedans, Chinese, or up-country Sikhs.

The result of this is that all the sedentary occupations are hopelessly over-stocked and underpaid and the educated classes and graduates of the universities, etc., have considerable difficulty in earning a living wage, while the illiterate classes can generally make a comfortable income.

This has a very real bearing on life insurance in the province, where the bulk of the population work daily in offices which are often overcrowded and ill-ventilated, and at night return to insanitary and often damp dwellings where they are frequently underfed and in consequence they readily become susceptible to diseases, such as malaria, dysentery and phthisis.

The more prosperous Bengalis on the other hand lead sedentary lives and usually take excess of carbohydrate food, so tend to become obese and to suffer from diseases which are usually associated with this condition, such as diabetes, carbuncle, etc.

Before passing on to discuss the statistics which I have compiled, I should like to make a few remarks on the general risks of residence in India and more especially in Calcutta. My attention was first drawn to this subject many

years ago by noticing in the obituary columns of the press the great age at death of many Europeans who had spent the major portion of their lives in India.

During the first four months of 1915 forty-nine deaths were recorded in one newspaper with an average age at death of seventy-three years. In this list were included the names of many well-known men who after a long and often strenuous career in India had reached a good old age. One in particular might be mentioned, namely that of Lord Roberts who after forty-one years in India died at the age of eighty-two full of mental and physical energy. Of course figures of this nature can be of no comparative value, they can only shew the age at death of those who have survived and they take no account of the deaths which have occurred during active life in India, but at the same time I think it will be accepted that they indicate that residence in India, especially for Europeans, is quite compatible with old age and often a healthy old age.

We of the present generation in India, and more particularly those of us who reside in the larger towns live under more congenial conditions and in more sanitary surroundings than our predecessors, amongst whom a considerable part of the heavy mortality was caused by what may be called accidental infections such as bacillary dysentery, enteric fever and Asiatic cholera, diseases which under modern conditions are becoming less prevalent and less fatal. The diagram (No. I) which I have compiled from the annual reports of the Health Officer to the

immediately felt. The epidemics which have occurred since this date are probably partly to be accounted for by the fact that in addition to filtered water there is also a supply of unfiltered water, which in the hands of a population largely illiterate and uneducated is always a source of danger. Epidemics may also be started by infected immigrants to the city and also by the importation of infected food, but these epidemics nowadays never become very serious. Another factor which in my opinion has a great influence in lessening the incidence of disease is the modern use of electric fans which became general about 1905. In the old days of hand-pulled punkahs it was unusual to get a good night's rest, the punkahwallah usually went to sleep shortly after his employer, with the result that mosquitoes and disease-bearing insects were given ample opportunities for causing disease and in addition abdominal chills with diarrhoea and dysentery, two frequent causes of death in India, were very much more prevalent than they are to-day. (*See Diagram No. III.*)

The following are the principal ways in which electric fans help to diminish disease:—

1. Their constant motion, especially at night, prevent mosquitoes, flies and other disease-bearing insects from infecting either man or his food.
2. They help to assist sleep and now it is rather exceptional for a healthy person to have a sleepless night, whereas in the old days of hand-pulled punkahs it was an unusual experience to sleep without being awakened on one or more occasions during the night. The punkahwallah was always inclined to work spasmod-

Diagram I.

Cholera Mortality Table for a period of Fifty-eight Years from 1865—1923.

Calcutta Corporation is interesting, as it shows the effect which the introduction of a filtered water-supply has had upon the cholera mortality in the city.

This filtered water first became available in 1869 when the cholera mortality was about 65 per 10,000 and its influence was almost

ically and his methods were a constant cause of chill on the abdomen, which frequently resulted in diarrhoea or dysentery.

3. Another beneficial effect that electric fans have is upon the temper, and I think there is little doubt that they have effected a lessening of that irritability which was formerly such a

well-known characteristic of European residents in India and was erroneously supposed to be due to hot curries. Constant want of sleep and annoyance at the vagaries of the punkahwallah, when continued over several months in each year, must have had a harmful influence upon the temper. It is a well recognised fact that the state of mind has an important effect upon blood-pressure and that fits of temper undoubtedly cause the blood-pressure to rise. The increased blood-pressure and nervous irritability when continued over long periods make themselves felt upon the arteries and in time cause thickening and possibly degeneration. Fortunately this is now a thing of the past and it is found that tropical residence with an actively perspiring skin tends to cause a low blood-pressure. During the hot weather and more especially during the rainy season it is not unusual to examine several men during one afternoon's work and to find that they all give a systolic sphygmometer reading well under 100 mm. Indians usually have low blood-pressures, but when one sees a large number of Europeans at certain seasons of the year with unusually low blood-pressure it seems reasonable to associate the condition with a climatic influence. Unfortunately, I have not at present sufficient data to support this clinical observation.

RESULT OF THE EXAMINATION OF 3,717 PROPOSERS.

These examinations have been conducted during the last ten years by my two partners, Drs. Adrian Caddy, Gordon Brandon, and myself. We have either made the complete examination ourselves or have revised the reports received from other examiners.

These cases consist of 1,473 Europeans and 2,244 Indians, most of the Indians being Bengalis.

In addition to these examinations, I have been able, through the kindness of the local representative of three large insurance companies which operate in Calcutta, to collect information with regard to 1,450 death claims, of which 1,117 occurred amongst Indians and 333 amongst Europeans. I shall refer more in detail to these death claims later.

We place the results of our examination and revisions into Classes A, B, C, postponed, or declined.

Class A consists of proposers of exceptionally good physique who shew no defects.

Class B are cases insurable at ordinary rates but they are not such good risks as those in *Class A*, owing either to poorer physique, indifferent past medical record, or some family defect.

Class C contain all proposers who shew more or less serious defects and who have been recommended either for a loading or for endowment policies of varying periods.

Class A contains 395 Europeans, 26.81 per cent. and 266 Indians, 11.87 per cent.

Class B contains 653 Europeans, 44.33 per cent. and 918 Indians, 40.9 per cent.

Class C contains 262 Europeans, 17.78 per cent. and 659 Indians, 29.37 per cent.

Postponed 113 Europeans, 7.67 per cent. and 218 Indians, 9.71 per cent.

Declined 50 Europeans, 3.39 per cent. and 183 Indians, 8.15 per cent.

From this it will be seen that comparatively few Indians come into *Class A* and that many more Indians than Europeans were either declined outright or were put into *Class C*.

The principal defects found were:—

Disease.	Indians. per cent.	Europeans. per cent.
Inferior physique ..	12	6.6
Obesity ..	8.9	3.3
Hydrocele ..	10.1	4.2
Heart disease ..	4.8	3.2
Lung disease ..	1.1	1.3
Albuminuria ..	2.2	1.09
Glycosuria ..	1.1	1.1
Bad family history ..	3.6	2.1
Enlarged spleen ..	0.9	0.3
Ear disease ..	0.9	1.09
Alcohol ..	0.0	1.2
Syphilis ..	0.9	1.7
Liver disease ..	0.08	0.8
Hernia ..	0.98	0.47

The points of interest which arise from this table are firstly the very great prevalence of hydrocele amongst Indians, secondly, many more Indians shew either inferior physique or obesity.

Albuminuria was also more prevalent amongst Indians, but I am rather surprised to find glycosuria present in the same proportion in both cases. This is probably due largely to the fact that most of the Indian candidates are comparatively young men and have not attained the age at which long-continued carbohydrate feeding has been able to produce glycosuria. My death claims, which shew that 4.9 per cent. Indians and 2.4 per cent. Europeans died of diabetes and allied diseases, rather support the inference. Alcohol and syphilis are as one would expect more prevalent amongst Europeans than Indians. The clerical classes are usually total abstainers and it is only the idle rich men and those who have been educated in Europe who take alcohol, which they frequently do to excess, also the lower classes drink large quantities of country spirit but they rarely come for insurance. Syphilis is comparatively rare amongst the better classes; they usually marry early and generally lead fairly moral sexual lives, among the lower classes on the other hand syphilis and other venereal diseases are exceptionally prevalent, so much so that doctors and nurses who work in Indian hospitals very frequently contract extra-genital infections.

HEIGHTS AND WEIGHTS.

I have here tabulated Indians and Europeans according to their heights and weights and for comparison in a separate column have shewn the

model weights given in Robertson's table. This table has been selected for comparison because it is the one we generally use in India and also because it deals more leniently with shorter men, who form the majority of Indian candidates.

Height.	EUROPEANS.		INDIANS.		Robertson's table model weight.
	Average weight.	Number of cases examined.	Average weight.	Number of cases examined.	
ft. in.	st. lbs.		st. lb.		st. lbs.
6 2	12 11	29	14 7
6 1	12 5	54	13 13
6 0	11 12	86	12 13	22	13 5
5 11	11 9	111	11 13	24	12 11
5 10	11 3	145	11 1	111	12 4
5 9	11 2	131	11 1	138	11 10
5 8	10 7	154	10 9	180	11 3
5 7	10 8	106	10 1	217	10 10
5 6	10 2	101	9 6	253	10 4
5 5	10 0	68	9 4	211	9 11
5 4	8 13	29	8 9	173	9 5
5 3	8 12	21	8 9	104	8 13
5 2	8 3	56	8 7

From these tables it will be seen that no Indians over 6 ft. came for examination, the majority of Indians were between 5 ft. 10 in. and 5 ft. 3 in., while most of the Europeans were between 5 ft. 11 in. and 5 ft. 6 in., so the Indians are on the whole rather shorter men.

At all heights Indians are considerably lighter than the normal, the figure 12 st. 13 lbs. at 6 ft. would probably have been lower if more men had been available, as it includes several unusually heavy men and even this figure is considerably lower than the normal.

The light weight for Indians is what I expected to find and it is important from an insurance point of view. Indians are always examined on the basis of the European standards as obtained from either Robertson's or Hutchinson's tables and so light weights are apt to be rather severely dealt with and conversely the normal weight of Indians being considerably lower than the standard heavy weight Indians are too leniently treated when we follow these tables. One frequently examines healthy young Indians who are men of reasonably good physique and is rather surprised to find that they scale many pounds below the minimum for their height. With regard to Europeans it will be seen that at nearly all heights they too are below Robertson's average and this light weight increases markedly when we come to examine the taller men. From the Indian examiner's experience this is not very surprising as it is a well-known clinical fact that Europeans when first coming to India tend to lose weight rather than to gain it and this applies more especially to the taller men, who do not seem to acclimatize so readily as smaller men, but even so Europeans in India are on the whole rather heavier than Indians.

AVERAGE HEIGHT AND WEIGHT OF INDIANS AND EUROPEANS AT DIFFERENT AGES.

In these latter the ages are divided into separate groups up to the age of 45 years, from 46 upwards they are all grouped together owing to the number of cases at these ages being comparatively few.

<i>Indians.</i>			
Age.	Height. in.	Weight. lbs.	Number of cases examined.
20 to 25	.. 65.74	126.33	290
26 to 30	.. 65.43	134.46	448
31 to 35	.. 66.76	150.54	336
36 to 40	.. 69.71	152.29	206
41 to 45	.. 66.50	150.50	83
46 upwards	.. 67.03	153.75	33

<i>Europeans.</i>			
Age.	Height. in.	Weight. lbs.	Number of cases examined.
20 to 25	.. 68.75	141.90	152
26 to 30	.. 70.74	145.24	264
31 to 35	.. 70.86	153.80	273
36 to 40	.. 68.22	156.97	210
41 to 45	.. 68.04	168.06	98
46 upwards	.. 67.86	146.94	53

The height of Indians in these different age groups is in all cases, except from 36 to 40, considerably lower than the Europeans, in most cases the difference amounts to several inches, which finding rather agrees with Caddy's figures given in his paper read before the Assurance Medical Society in 1912.

Also the average weight of Indians in each of these age groups is considerably lower than the weight of Europeans until the maximum age 46 years and upwards is reached when it becomes markedly greater, although in height the Indians are rather shorter men.

The light weight of Indians is particularly marked in the younger age groups and one's clinical experience rather leads one to expect this. Young Indians are generally thin and comparatively tall but in later life if they become at all prosperous, they usually incline to obesity, whereas Europeans as a rule tend to lose weight after long residence in India.

When we are considering the influence of height and weight upon life insurance, it is interesting to study Rabagliati's paper, which was read before the Assurance Medical Society in 1915. In this paper he quotes figures published by the Actuarial Society of America which deal with some 812,221 policies and which shew that underweight in early life has graver consequences than it has in later life, when it is rather an advantage than otherwise.

Those insuring at ages 20—24, who were 25 to 45 lbs. under weight showed an actual mortality

of 134 to 100 of the expected mortality and among those insuring at ages 25 to 29 years the actual mortality was 116 to 100 expected.

In latter life, on the other hand, the results are quite different, amongst those entering at ages 50 to 56 and showing the same amount of under weight the actual mortality was only 91 per cent. of the expected, and of those at ages 57 to 62 it was only 81 per cent.

Overweight has quite a different influence at all ages. A marked overweight has a bad effect at all ages, but it is less marked at the earlier ages than at the later ones.

With regard to height the same authority states that at younger ages tall men have proved to be less desirable risks than short men, whereas at older ages short and medium sized men have been the slightly worse risks.

I too have found that young Europeans who are exceptionally tall are not good risks, they frequently do not acclimatize well and often have to be sent home physically unfit to live in the tropics.

I propose now to discuss in detail some of the more important diseases which have to be considered in connection with life insurance work.

Disease.	Indians. per cent.	Europeans. per cent.
Pneumonia	12.2	9.6
Heart failure	7.9	15.9
Apoplexy	5.2	4.1
Phthisis	6.9	3
Diabetes (including carbuncle)	4.9	2.4
Liver diseases (including abscess)	4.2	3.6
Undifferentiated fevers	3.04	1.2
Kala-azar	0.9	0
Malarial fever	2.8	0.6
Enteric fever	4.2	3.9
Dysentery and diarrhoea	5.1	2.7
Cancer	1.07	3.3

With the exception of heart failure and cancer, the percentage of claims made by Indians for all these diseases is markedly greater than those made by Europeans.

RESPIRATORY DISEASES.

In Calcutta during 1923 these diseases accounted for the death of no less than 6.7 per thousand of the total population, the most fatal diseases being phthisis, pneumonia and bronchitis.

PHTHISIS.

Rogers gives figures from the post-mortem records of the Medical College Hospital,

Diagram II.

Diagram II has been taken from the latest available annual report (1923) of the Health Officer to the Calcutta Corporation and shews the total number of deaths which occurred in the city from twelve of the principal diseases during that year. It will be seen from this table that respiratory diseases and dysentery cause the greatest mortality.

My death claims which will be referred to from time to time have been compiled so as to shew the percentage mortality from the more important diseases as they affect Indians and Europeans. They include 1,117 Indians and 333 Europeans death claims:—

Calcutta, which shew that 16.1 per cent. of the cases examined by him were due to phthisis. The Health Officer states that the tuberculosis death-rate is 2.3 per 1,000 of the population and further he shews that nearly all the tuberculosis deaths are due to phthisis. In 1923 this disease accounted for 2,089 cases or 94.2 per cent. of the total tuberculosis deaths, which leaves only about 6 per cent. for surgical tuberculosis and other types of bovine origin, whereas in London 20 per cent. of the tuberculosis deaths are due to these types.

This absence of bovine tuberculosis in Calcutta where cattle are usually free from tuberculosis,

is not altogether an unmixed blessing, it probably accounts for the fact that phthisis amongst Indians runs a very acute course. The Health Officer states that it is probable that the great majority of Indian phthisical patients die not later than one year after the first symptoms appear.

In this connection it is interesting to note that Powell in Bombay conducted 8,000 post-mortems on Indians and only found signs of old phthisis in 2.3 per cent. of his cases, whereas in the United Kingdom no less than 85 per cent. shewed signs of old infection. The difference is probably due to the absence in India of minor immunity-establishing infections from tuberculous milk and this absence of immunity may possibly account for the acute type of disease found in Indians.

Amongst Indian women phthisis is especially prevalent, the majority of women adhere to the *purdah* system which usually necessitates their living in ill-ventilated and insanitary buildings with little or no access to the outside world.

In Calcutta the death-rate amongst women is always higher than amongst men, whereas in London it is the men who always suffer more severely. This point is emphasized in the following figures which have been collected by Dr. Mazumdar of the health department of the Calcutta Corporation for the last ten years:—

		Tuberculosis Death Rate amongst males per 1,000 living.	Amongst females per 1,000 living.
1914	..	1.8	3.6
1915	..	1.6	3.2
1916	..	1.3	2.6
1917	..	1.3	2.5
1918	..	1.6	2.9
1919	..	1.6	3.2
1920	..	1.7	3.6
1921	..	1.8	3.7
1922	..	1.7	4.0
1923	..	1.6	3.7

The increase during the last five years is probably the aftermath of the severe influenza epidemic in 1918.

Taken as a whole the figures shew conclusively that the death-rate from tuberculosis has remained fairly constant during the last ten years, whereas in London it has shewn a fairly steady decline and during the last 80 years it has fallen from 3.5 per thousand to 1 per thousand.

My own death claim figures shew that amongst Indians phthisis accounted for 6.9 per cent. of the total deaths while amongst Europeans it was only 3 per cent.

The causes of this heavy incidence amongst Indians are chiefly:—

1. Insanitary housing conditions with lack of fresh air and sunlight, which is aggravated by overcrowding and the retention of the *purdah* system in a city densely populated.
2. Promiscuous spitting in an atmosphere often dry and dusty.

3. Underfeeding.

4. I have already mentioned the infrequency of minor infection with bovine tuberculosis, which must also be considered a cause.

5. General susceptibility of Indians to pulmonary disease.

PNEUMONIA.

Lobar and broncho-pneumonia in Calcutta accounted for rather more than 3,000 deaths in 1923.

Lobar pneumonia in particular is a very fatal disease amongst Indians, the mortality being almost as great as that from phthisis.

Rogers' post-mortem records shew that in 16.03 per cent. of his cases death was due to lobar pneumonia, while the Health Officer gives it as the cause of death in 1.9 per thousand of the population and further he states that it is essentially a disease of the prime of life, no less than 37 per cent. of the deaths occurring between the ages of 21 and 40 years.

The race incidence was highest amongst Hindus, distinctly lower amongst Mahomedans, and much below the average in Europeans. My death claim figures shew that 12.2 per cent. of deaths occurred amongst Indians, whereas only 9.6 per cent. were amongst Europeans.

A considerable number of cases of pneumonia in Indians terminate in gangrene of the lung, which fact suggests a low resisting power amongst them to inflammatory conditions of these organs.

There is a well marked seasonal incidence, 42 per cent. of deaths occur in the four coldest months, November to February; 31 per cent. in the very hot weather months, March to June; and 27 per cent. in the rainy months, July to October.

DYSENTERY AND DIARRHŒA.

Under this heading are included dysentery, diarrhœa, enteritis and puerperal diarrhœa known to Indians as *sutika*.

The attached Diagram III taken from the Health Officer's returns shews the number of deaths from these diseases per 10,000 of the population during the last twenty years, from which it will be seen that bowel complaints are much less fatal now than they were in the earlier years, but that even now they account for a large number of deaths every year. In 1923 no less than 3 per 1,000 of the population of Calcutta died from them.

	Deaths.
Dysentery accounted for	1,677
Diarrhœa " "	958
Puerperal diarrhœa " "	99

The mortality figures shew a well marked double curve of seasonal prevalence. The first reaches its height in March and the second, a much larger one, in August, during which month they accounted for no less than 4.4 per thousand of the total population, the lowest mortality is in the hot weather months of May and June,

which are well known to be the most healthy months to residents in Calcutta.

The suburbs always suffer more severely than the centre of Calcutta owing to the large number

Also chronic malarial infection and kala-azar frequently affect the liver in both races and they are more prevalent and severe amongst Indians than Europeans.

Diagram III.

[Diarrhoea and Dysentery Mortality Table, Calcutta, 1894—1923.

of service privies in them, which pollute soil and water and afford facilities for the contamination of food through the agency of flies. This condition obtains throughout all Bengal.

Mahomedans seem to suffer most severely and Europeans least, the low figure for non-Asiatics 2.2 per thousand is probably due to the fact that they usually live under better hygienic conditions.

My death claims also shew that Indians suffer more severely than Europeans, the figures are 5.1 per cent. and 2.7 per cent., respectively.

The highest mortality occurs at the extremes of life, chronic dysentery and diarrhoea being especially prevalent and fatal in old age.

DISEASES OF THE LIVER, INCLUDING ABSCESS.

My death claims shew that 4.2 per cent. Indians and 3.6 per cent. Europeans died of liver disease.

It is rather surprising to find so many claims arising from Indian cases as the bulk of the better class Indians, who are the insuring class, are total abstainers. Lower class Indians undoubtedly drink large quantities of country spirit, which is very impure and intoxicating, so it is not surprising to find liver diseases frequently amongst them.

On the other hand high class Indians, especially Hindus, in addition to being total abstainers are also vegetarians, so amongst them some non-dietetic cause must be looked for and it seems possible that chronic rectal ulceration, usually dysenteric, may be a factor in producing both acute hepatitis which frequently goes on to abscess formation and also a chronic hepatitis which may possibly cause the liver to become cirrhotic.

FEVERS.

Diagram IV shews the fever mortality in Calcutta during the last thirty years.

It includes deaths from the following fevers:—

1. Malaria and kala-azar.
2. Remittent and undifferentiated fevers.
3. Probably a certain number of atypical cases of well-known fevers as enteric, pneumonia and even tuberculosis.
4. Other well-defined fevers which would be correctly diagnosed by well-qualified doctors.

It will be seen that there has been a marked decline in the fever mortality during the past thirty years, but it is probable that the reduction has not been so great as would at first sight appear. Owing to improved methods of diagnosis more diseases than formerly are now being classified under their proper headings. There is, however, no doubt that fevers, especially malignant malaria and kala-azar are very prevalent in Calcutta, which is an ideal city for their spread and especially so for malaria. The atmosphere is hot and damp for many months in the year, foul tanks with decomposing vegetable matter are found in abundance, and in addition the subsoil water is usually at a high level. These conditions obtain in practically all parts of Bengal, where they are even more marked than in Calcutta itself.*

* Calcutta city itself is not very malarious, but its environs are, and many of the Indian clerical class concerned live in the environs. Dr. Napier has shewn that kala-azar in Calcutta city spreads in and around Ward 14, but not elsewhere. On the other hand conditions in the environs of Calcutta and in Bengal generally are ideal for the spread of both diseases.—Editor, *Indian Medical Gazette*.

Malaria has a well-marked seasonal prevalence, the incidence being greatest in the months of October and November and declining to a minimum in the hot and comparatively dry months of April and May.

which 2,330 were for the radical cure of hydrocele, or 83 per cent.

The majority of these hydroceles were much larger than the ones usually operated upon in European hospitals for the simple reason that

Diagram IV.

Fever Mortality 1894-1923, Calcutta.

All fevers affect Indians to a greater extent than Europeans; this is probably due to their living in the more unhealthy parts of the city and of the presidency generally.

My death claims shew how markedly different this racial mortality is:—

Deaths.	Indians. per cent.	Europeans. per cent.
Fevers (undifferentiated)	.. 3.04	1.2
Kala-azar	.. 0.9	0
Malaria	.. 2.8	0.6
Enteric fever	.. 4.2	3.9

HYDROCELE.

In books on life insurance very little notice seems to be taken of this disease, which is extremely common amongst Indians, much more so than amongst Europeans.

The result of my examinations shew that 10 per cent. of all Indians examined have hydrocele, whilst amongst Europeans it was only found in 4.2 per cent. of the cases.

My figures would have shewn an even smaller proportion amongst Europeans, had not Jews been included amongst them. The Jews examined are really more closely allied to Asiatics than Europeans, as they chiefly are Armenian Jews from Baghdad. Without them the European figures would have shewn only 3.1 per cent.

The operation figures taken from a small Indian hospital to which I am surgeon-in-charge bring out very clearly the extreme prevalence of this disease amongst Indians. During the last eleven years from 1914 to 1924 we have performed at this hospital—excluding gynaecological and eye cases—2,798 major operations, of

the Indian will not submit to operation until his hydrocele is sufficiently large to interfere with locomotion or until his penis has almost disappeared in the swelling.

In addition to these hydrocele operations we have removed 112 scrotal tumours of filarial origin most of which contained large double hydroceles.

It is true that the risk of operation is not very great, amongst these 2,330 operations we have had only two deaths, but it must be remembered that in a hot country like India where the skin of the scrotum is generally heavily infected with organisms of suppuration, often superimposed upon a chronic scabetic infection, many hydroceles suppurate from trivial causes and it is not uncommon to find the suppuration causing death before operation is performed.*

I am of the opinion that most companies treat hydrocele risks rather leniently. They usually accept cases of single hydrocele, unless very large, at ordinary rates, while for double hydrocele they require only a small loading of $\frac{1}{4}$ per cent.

GLYCOSURIA.

Glycosuria in India as in England is a common cause for declining or postponing proposals and in many cases it is a little difficult to know quite how to deal with them, especially so when the proposer is a young and obviously healthy man. It is astonishing how frequently young healthy Europeans who reside in the tropics

* Acute funiculitis—often of filarial plus streptococcal origin—is a very fatal disease, and is probably another factor involved.—Editor, *Indian Medical Gazette*.

exhibit glycosuria after some temporary indiscretion in diet, so much is this the case that when I find sugar in a European during an afternoon examination I always enquire into his diet for lunch and I generally find that, not wishing to create a false impression by smelling of alcohol, he has taken ginger beer instead of his usual whisky and soda. Of course the amount of sugar contained in one or perhaps two bottles of ginger beer should not normally be sufficient to come near the renal excretion threshold but possibly a tropical climate may have some influence in lowering this threshold and also most Europeans who live in India hold responsible positions which usually entail considerable worry.

These cases to which I am now alluding are on subsequent examinations practically always free from sugar, but still, having once found sugar, one has to regard them with suspicion.

The present course adopted by many insurance companies who insist on three negative examinations is to my mind unscientific. It is unfair to the proposer as it makes no attempt to differentiate true diabetes from renal glycosuria with its low excretion threshold and also it is unfair to the company in so much that a knowledgeable man will consult his doctor and may often free himself from sugar by treatment.

From an insurance point of view the important point to discover is the condition of the blood sugar. It is very simple and inexpensive to get this done, and in my experience proposers will readily consent to have the examination made, often at their own expense, if the necessity for it is explained to them.

It is now well recognised that proposers with a high blood sugar may shew little or no glycosuria, while others with normal or low blood sugar may shew a frank glycosuria.

In this connection it is interesting to note that Indians who are vegetarians tend to have a higher blood sugar than non-vegetarians (Bhatia, *Indian Medical Gazette*, December, 1925). This observer also noticed that estimations made in the morning gave a lower figure than those made in the afternoon about four and a half hours after the morning meal. Sugar excretion is apt to be modified by defective kidneys, so faint traces of glycosuria in middle or advanced age may be an indication of a high blood sugar, and in consequence should be treated with suspicion.

In conclusion, I would like to draw attention to the result of my own examinations which shew that glycosuria was found amongst Indians and Europeans in an equal percentage of cases (1.1 per cent.). This is rather surprising as it has always been thought that Indians, and more especially Bengalis, were very susceptible to glycosuria, but perhaps it may be accounted for by the fact that it tends to appear in Indians late in life and that the majority of the cases examined were those at a comparatively young age. My death claims shew that diabetes and

allied diseases such as carbuncle accounted for 4.9 per cent. of Indian deaths and only 2.4 per cent. of European deaths.

KIDNEY DISEASES.

According to Rogers these diseases are less frequent in Bengal than in London, which fact he attributes to the greater incidence of acute parenchymatous nephritis and granular kidney in London.

One would expect Indians and especially Hindus, owing to their vegetarian diet and the general absence of scarlet fever in the plains, to be comparatively free from diseases of the kidney. Also the activity of the skin during the hot and rainy seasons must decrease the amount of toxins which pass through the kidneys, and as I have already shewn it has a marked lowering effect upon the blood-pressure especially during the rains.

In England kidney disease with high blood-pressure and arterial degeneration is a common cause of death, but the practitioner in India does not seem to meet with this class of case so frequently as he does when practising at Home.

Perhaps to a certain extent this may be accounted for by the fact that Indians die from other diseases at an earlier age than Europeans and do not so frequently attain the age at which granular kidney develops. On the other hand Indians frequently have albuminuria, my figures shew that 2.2 per cent. of Indians were either loaded or declined on account of albumen whereas only 1.09 per cent. of Europeans were similarly treated, but then the presence of albumen does not necessarily indicate disease of the kidney, and unless kidney efficiency tests are done or some other clinical manifestations are present it is not possible to say how much of this albuminuria is due to actual disease of the kidney.

The present custom of many insurance companies who require three urine tests to be free from albumen is on the whole a fairly good one, because within the limits of an insurance examination it is not possible to carry out the elaborate tests which are required to make an accurate investigation into the cause of the albuminuria.

DISEASES OF THE HEART.

The two chief causes of valvular disease of the heart and of endocarditis and pericarditis which are so frequently found in Europe, namely acute rheumatism and scarlet fever, are exceedingly rare in the plains of India.

Rogers, writing in the *Glasgow Medical Journal*, in January 1925, compares the post-mortem records at St. Mary's Hospital, London, with those of the Medical College, Calcutta, and finds that circulatory diseases are twice as common in London as in Calcutta. He attributes this to the almost entire absence of rheumatic endo- and pericarditis in Bengalis; on the other hand malignant endocarditis was frequently found in Bengal and in many cases the

pneumococcus was found in the diseased valves. This is not at all surprising when we consider how frequent and how fatal pneumonia is amongst Indians.

Basu writing in the *Indian Medical Gazette* concludes that chronic endocarditis is less frequently found in Indians than in Europeans, but on the other hand myocardial degeneration is very prevalent and is largely responsible for the early death of the people. The cardinal factor for this mortality is climatic which causes vasodilation and by throwing greater work on the heart draws largely upon the cardiac reserve, which owing to poverty of food and chronic infections such as malaria, dysentery, kala-azar and beriberi, is at the best of times never very great. Beriberi and epidemic dropsy in particular cause heart symptoms with tachycardia which often persist in spite of all treatment for many years. In my list of death claims it will be seen that heart failure is found to be twice as frequent in Europeans as in Indians, 15.9 per cent. against 7.9 per cent. but apoplexy on the other hand is rather more frequent in Indians 5.2 per cent. against 4.1 in Europeans.

Possibly this may be accounted for by the fact that Indian syphilitics do not undergo very thorough treatment for this disease.

PYORRHOEA.

Pyorrhœa is extremely prevalent in the tropics and especially so amongst Indians, it usually begins as an inflammation of the gum margins, which gradually spreads to the bony sockets of the teeth and causes them to become loose and eventually to fall out, unless the tartar which usually appears, and is seldom removed, is sufficiently hard to form a splint.

Bodley Scott in the course of investigations amongst prisoners in the Sylhet jails found that at the age of 25 years only 50 per cent. have healthy gums and that this number gradually decreased until at the age of 55 only 6 per cent. were free from the disease. The incidence seems to be most marked in the hot weather months which rather suggests that general health may have some bearing upon it.

Another factor which may possibly be the starting point is a local infection of the gum margin. It is the custom amongst many Indians to pick up any piece of stick, preferably a piece of *neem* stick, and to make it serve as a combined toothbrush and tongue scraper, which to my mind is usually the starting point of the infection.

In spite of the extreme prevalence of pyorrhœa amongst Indians many diseases supposed to be secondary to a focal infection such as appendicitis, gastric and duodenal ulcer and rheumatoid arthritis are extremely rare amongst them, on the other hand muscular rheumatism, lumbago and dyspepsia are common.

Many insurance companies do not care to accept cases with marked pyorrhœa, but as the slight cases practically always are progressive,

especially so amongst a race who seldom have dental treatment, if one did not treat the condition leniently very few Indian proposals would be accepted.

CONCLUSIONS.

1. The risk of Indian residence is steadily decreasing for both Europeans and Indians.

2. Taken as a whole Indians are considerably worse risks than Europeans and insurance companies probably act wisely when they encourage endowments rather than whole life policies for Indians.

3. Indians are usually men of shorter stature than Europeans and their corresponding weights generally are lower.

This is particularly noticeable in the younger men, but older men are inclined to become heavier than Europeans. Indians who are overweight should be regarded unfavourably, they are generally prosperous, lead sedentary lives, and eat carbohydrates to excess.

4. Respiratory diseases and more particularly pneumonia and phthisis are very fatal diseases for Indians. The phthisis mortality shews no tendency to decline and the disease is usually of a very acute type. It is more fatal for women than men, probably owing to the *purdah*.

5. Dysentery and bowel complaints are very fatal for Indians but the mortality from these diseases has declined considerably during the last thirty years.

6. The mortality from fevers declined rapidly in Calcutta up to 1908, since when it has remained fairly constant.

7. Hydrocele is especially prevalent amongst Indians and is an occasional cause of death.

8. Glycosuria is not very prevalent amongst Indians until they reach middle age, after which its incidence increases and it becomes more fatal for Indians than for Europeans. Indians tend to have a higher blood sugar than Europeans.

9. Owing to the infrequency of acute rheumatism and scarlet fever, valvular disease of the heart is not so common amongst Indians as amongst Europeans, but malignant endocarditis and myocardial degenerations are common.

10. Pyorrhœa is very common amongst Indians, so much so that after middle age few seem to be free from it.

PRINCIPLES IN THE TESTING OF A CURE.*

By HUGH W. ACTON,

MAJOR, I.M.S.,

Professor of Bacteriology & Pathology, Calcutta School of Tropical Medicine & Hygiene.

THE lay public consider that all that is required in testing the value of a supposed "cure" for a disease is to give the drug, and if there is any improvement (whether it be temporary or permanent) then the drug is considered to have been sufficiently tested on this single case, and to be a cure for the disease. That such an idea is universal amongst the lay public is seen from the advertisements in our daily papers, and we can readily understand the layman's point of view. But why a similar belief should be so prevalent amongst medical men, and why they should adhere to it for so many years on end, it is difficult to understand. This remark applies with still greater force to medical research workers, who ought to be acquainted with modern biometrical methods. Most workers in India have not as yet appreciated how much we owe to Lieutenant-Colonel W. F. Harvey, C.I.E., I.M.S., for his introduction of mathematical and biometrical methods into the study of rabies and allied diseases in India.

At present we see in our medical journals papers based on a series of two or three cases successfully treated by one drug; to be followed in a short time by another author who refutes the value of the first drug, but extols a second one on equally scanty evidence. At times one's head whirls as one reads through present-day medical literature and comes across a disease with at least thirty different cures for it, but with no indication as to when any particular one of them should be employed in the disease. Sir Kingston Fowler, K.C.V.O., M.D., in his clinics taught that when a disease has a host of cures, there is no cure for it. I am sorry to say that I now disagree with his views, but when there is a host of cures for one and the same disease, the position really is that we do not know definitely how these different drugs act on the system. Take, for instance, the value of atropine and cocaine in vagotonia, and of adrenalin in sympathicotonia; they are excellent as temporary remedies, but they do not cure the two types of asthma concerned. In this country we have two "systems" of medicine for which exaggerated claims are made by their supporters, the Ayurvedic or indigenous system, and homeopathy. There can be only one system of medicine, that which enables us to make a sure diagnosis, and gives a remedy which is a safe and efficient cure for the particular disease. We must also realise that our tissues have been given certain defence mechanisms in order to fight the diseases that attack our bodies; and that natural cures do not occur in an instant, but require time in order to develop, though they are usually extremely efficacious. For this reason, the last remedy to come to hand often seems to us to have been the one most effective in bringing about a cure.

When we come to a still more difficult subject, such as to assess the relative values of two different salts of the same metal, or of two almost identical alkaloids, as we shall see later, very large numbers of tests under identical and controlled conditions are requisite before any definite opinion can be given one way or the other.

The time has come when we should survey the position rationally, instead of making claims for this, that or the other drug upon wholly insufficient evidence.

The Action of Drugs.

If we ask ourselves the pertinent question, how do drugs act, we will see that even to-day very little is

known about their real effects upon the body or upon the parasitic causes of disease.

Drugs may be classified into two groups:—

(1) *Specific drugs.*—These act upon the parasites in doses which are non-lethal to the human host; and they may again be sub-divided into two groups:—

(a) Drugs which act selectively—and possibly directly—upon the parasites; such as the use of quinine in malaria, and of emetine in amoebic dysentery. Our recent work has shewn that, to be efficacious, the site of greatest concentration of such drugs within the body should coincide with the site of most rapid multiplication of the parasite concerned. Moreover the absorption and concentration within the body is increased or decreased by changes in the pH of the gut; also such drugs act best in an alkaline substrate. They probably act by interfering with the movements of the parasite, or by rendering its food supply from the tissues distasteful to it; for instance it has been shewn by Dale and Dobell that *Entamoeba histolytica* will not ingest emetinised red blood corpuscles.

(b) *Specific drugs* which act only indirectly upon the parasite, but which are specific cures for the disease; for example, the use of arsenical derivatives in syphilis, and of antimony compounds in Leishmania infections.

(2) *Empirical Drugs.*—These are not specific cures for an infection with a given parasite, but are given empirically. Many of them stimulate the defence mechanisms of the body in one way or another, and so bring about a cure. Diseases such as asthma are not true diseases but are symptom-complexes, clinical entities caused by a whole host of different causes. We see therefore that in the cures advocated for asthma there are at least 20 to 30 drugs which have been used; each having its own value in a given case, and acting either temporarily or permanently. The cure rate with these empirical drugs will always be low, because they will only act if the exact defence mechanism concerned is not paralysed, is capable of responding, and can be stimulated.

This brief account will show that we are a long way from understanding how drugs act, but we can see clearly that if our diagnosis is correct, it is with the specific drugs that there will be the greatest probability that cure will occur. With empirical drugs we place the lucky sign of Jupiter at the head of our prescriptions, and hope that chance or luck will favour our efforts.

The Mechanism of Cures.

Now cures can be brought about in two ways:—

(1) *Naturally.*—In bacterial diseases we have tissue-response to the invasion, with the production of anti-substances, and finally the establishment of a definite immunity. In protozoal infections, there may be a special association between the species of host and parasites; thus the malarial parasites attack only man, and can only—and that only as a transient infection—be transmitted to the higher apes; on the other hand there is often a close association of groups with genera; thus the (true) Leucocytozoa are parasites only of birds. With repeated attacks however, and with age, a relative immunity—or perhaps, more strictly speaking, a tolerance—may be acquired; for example the difference in incidence of febrile attacks of malaria as between children and adults in an endemic malarial area.

(2) Secondly, cures can also be brought about artificially. In bacterial diseases we may bring about artificial cure by conferring active or passive immunity. In protozoal diseases we have many specific drugs, such as quinine, emetine and antimony; in the case of spirochætal infections, the derivatives of arsenic. We can also bring about a cure by raising the internal defence mechanism by good feeding, the administration of endocrines, etc. Now all these factors, such as race, age, susceptibility, and the state of the internal defence mechanism, play their part in cure; and if we neglect them we may find that our population under treatment

* Being a paper read at a meeting of the Medical Section of the Asiatic Society of Bengal on Monday, the 12th April, 1926.

[Note.—We regret that owing to a mistake on the part of the press, Major Acton's article has been set up in small type.—EDITOR, *Indian Medical Gazette*.]

with the supposed cure, and our untreated control population, are made up of two groups which are very dissimilar.

All diseases cause injury to the tissues upon which they act. We may have:—

(1) Injury, with complete recovery, as in measles, mumps, etc.

(2) Recovery, but with permanent impairment of the functions of an organ. Thus the damage to the heart after endocarditis, or to the kidney after nephritis must always be permanent: such damage may be likened to a permanent scar upon the cutaneous tissues.

(3) Lastly, we may have recovery, but with permanent loss of function. This is most commonly seen when the central nervous system is attacked, as in hemiplegia, lathyrism and other paralyzes.

So we see that, although recovery may take place, yet there may be permanent damage left; under such conditions it may be very difficult to assess the value of a cure,—for instance in the treatment of nerve leprosy.

Kinds of Cure.

Now cures may be of two kinds. They may first of all be *permanent* and associated with more or less complete immunity, such as is seen in the specific fevers, and in such bacterial diseases as typhoid fever. On the other hand, the cures may only be a *temporary* matter, with a reduction of the number of parasites to a level insufficient to cause symptoms, but without their eradication; as in malaria and syphilis. In syphilis the involvement of the central nervous system may come on many years after the initial lesion, in the form of tabes or general paralysis of the insane. Again, in hereditary diseases such as asthma, where a lowered internal defence mechanism may be inherited, but can be raised artificially by treatment, any debilitating condition may cause this syndrome to appear. In these diseases *time* becomes a very important factor in determining whether a patient is or is not cured. It is for this reason that we cannot yet determine the relative merits of the different arsenical compounds in the treatment of syphilis; they have not yet been in use over a sufficient period of years to demonstrate their final value. If it can be shewn subsequently that their use has lowered the general incidence of tabes and of general paralysis of the insane, then we shall be in a position to gauge their relative efficiency.

Before we can pass on to discuss the different methods which we have for testing a cure, we must first know the following facts:—

(A) The *ætiological* factors that may affect the homogeneity of the population which we have under test. The first important factor under this heading is *age*. You all know how age affects the probable duration of life. It is on this that all insurance tables are based; each year up to middle life means an additional increase in the resistance of the individual, each year beyond it a diminished resistance. Again *hereditary* factors come in, such as race, family and sex; these all play their part in the incidence of and resistance to certain diseases. The third important factor is *environment*. This is important in tuberculosis and leprosy, where the person at risk often lives in contact with other diseased individuals; or in malaria or kala-azar where a cured patient may become re-infected when he returns after treatment to the same environment in which he first contracted the infection. In such diseases, tests for a cure should be conducted only in non-infective areas.

You can see how hopeless it would be to treat malarial cases with one or other cinchona alkaloid in an infective area, where one group of persons being treated with alkaloid A was being observed during the off-season, and a second group B during the infective season. The way to test the value of a cure for malaria is to take the patients out of the infective area, e.g., to the hills, and to conduct the observations in a non-endemic area.

Under the heading of environment we have also to

consider the occupation, habits and customs of the individual. Lastly, there are the *effects of concomitant and debilitating diseases*; thus leprosy or kala-azar is more difficult to treat when complicated by syphilis; and the anemia in a case of malaria may also be partly due to heavy hookworm infestation, treatment of which is just as necessary as of the malaria itself. It is not difficult to see how these factors may affect the composition, either of the population under test, or of the controls, and so cause variation.

(B) Secondly, we must also know the *untreated mortality rate* for the disease in question. This is closely bound up with the above mentioned *ætiological* factors. For example, the mortality rate in such a disease as pneumonia will always be a small one in such a selected population as the army, since the men concerned are in the prime of life, between 20 and 45 years of age, well fed, and have regular exercise. On the other hand, in a civilian hospital population which includes the young, the old and the debilitated, the mortality rate for pneumonia will always be higher than in the army. Any treatment in the army group would always give better results than in the civilian hospital group. At present in pneumonia we can only depend on indirect remedies, such as heart tonics, nursing, etc., and in estimating their success we are therefore relying on partial correlations.

In some diseases the natural mortality rate is very low. For a general dog-bite population as treated at any Pasteur Institute,—and which includes persons bitten by rabid and non-rabid animals, by infective and non-infective animals, persons at real risk, and others at no risk at all,—I would not put down the mortality from hydrophobia among the untreated at more than 2.5 per cent. among a homogeneous population. In India cases of bites from non-poisonous snakes far outnumber cases of bites from poisonous snakes, whilst, for many reasons, a poisonous snake may often fail to give a lethal dose of venom; hence I would not assess the mortality from snake-bite amongst all persons bitten at more than 7 per cent. in untreated cases. These low natural mortality rates give ample scope for any and every kind of quack treatment, as the natural cure rates are very high. The general public look upon every case of bite from a presumably rabid dog, or from any kind of snake, as necessarily fatal unless treated, and any case of recovery to be a cure; hence any remedy employed will be called a cure, no matter how worthless it may prove to be when tested under rigid experimental conditions in the laboratory. Again, there are epidemic diseases such as small-pox and cholera where the mortality rate varies enormously with the particular epidemic concerned, and even during the course of the same epidemic. Thus whether alastrim, with its very small death rate, is or is not small-pox, it is difficult to say. There is at least one disease in man, on the other hand, which is always fatal, no matter what remedies are employed, and that is hydrophobia.

Errors in Assessing the Value of Figures.

Before we can test whether a particular line of treatment is or is not successful, we must first eliminate any errors that may arise in the composition of the population concerned. The first error, and a very important one, is that produced by *bias*. We may take it for granted that every medical man is sufficiently honest not deliberately to alter his figures. There is, however, an element of bias which is often carried out unconsciously when dealing with the controls. Monsieur Pasteur himself in his anti-rabic experiments committed this error unconsciously, when he placed among his "treated" dogs those untreated animals which had already survived the test by subdural inoculation of rabies virus. One is more apt to place among the controls any case that may possibly increase the mortality rate among the untreated. The way to avoid this very important error is to take cases in turn alternately and place them in the two groups without any selection. Even in spite of such care, some selection will occur, as we shall presently see. The safest way to prevent

this unconscious bias is to be if anything more favourable to the controls than to the treated group, because if the remedy tested has any value at all, its value should become apparent in spite of any bias favourable to the controls.

A natural selection also occurs owing to the *law of chance sampling*. If a coin is spun 100 times, on an average heads should turn up 50 times, and tails 50 times. Yet in any actual series of 100 spins we may get a marked preponderance of heads or of tails. If, among the untreated, heads represent recoveries and tails deaths, we see that a disease which has a natural death rate, let us say, of 25 per cent., may thus be profoundly affected, especially if the number of observations made is small. I will now give you three illustrations of how such random sampling may affect results:—

(1) Chart II (*vide* p. 276) gives the number of deaths from snake-bite which have occurred amongst the British army, the Indian army and the jail population in India during the years 1890-1925. (The figures for the years 1911 to 1919 are missing, as they are not given in the annual returns of the Public Health Commissioner, India). The first point with regard to these figures is that the mortality rate in snake-bite in general is a small one, 7 per cent.; this means that bites from all sorts of snakes, including a preponderance of bites from non-poisonous snakes, are included; 93 out of every 100 persons bitten escape death. To the general public this means that any remedy employed becomes a cure. If to this "cure" rate we add various difficulties in obtaining the drug, upon which the vendors of quack remedies so often insist, such as that it must be collected at a certain time of day, at a certain place, or in a certain season, or by the light of the moon, etc., so as to make it very difficult to obtain the remedy when a case of snake-bite has occurred we see that the "cure" becomes even more effective. The result is that those who are bitten and into whom a fatal dose of venom has been injected, die early; they cannot obtain the "cure" sufficiently early to save life; these deaths therefore pass into the group of untreated controls, and swell the mortality in this group; on the other hand the persons who will survive in any case, survive to obtain the "cure," and the absence of mortality among them lowers the mortality among the treated group. Even genuine investigators often fall into this error.

TABLE I.

Showing the effect of the lateness of arrival at a Pasteur Institute on the efficacy of the treatment.

Days late.	KASALI 1924. (c)	(b) MCKENDRICK.			(a) HARVEY AND ACTON 1912.
	All cases.	Face.	Arm.	Leg.	All cases.

29—35	0.90				0.3
36—42	2.94				
43—49	2.56				
50—161	Nil 52 cases.				

(2) Table I gives figures shewing the effect of lateness of arrival on the mortality rate from hydrophobia among patients treated at the Pasteur Institute of India,

Kasauli; (a) during the years when Colonel Harvey and I were in charge; (b) when Major McKendrick was in charge; and (c) when Major King was in charge.

When a Pasteur institute first opens its mortality is generally a high one. This is because at first it only attracts bad cases, i.e., those who have been really bitten by really rabid animals. By degrees, as knowledge of the institute spreads and of the facilities offered, more and more persons who are less and less at risk come for treatment; persons bitten by non-rabid or non-infective animals, persons who are merely licked and not at risk at all, persons even who do not know whether they have been licked or not. Hence with an increasing element of those not-at-risk, the natural tendency is for the mortality rate to decline steadily, no matter what is the treatment given.

Further, lateness of arrival affects these figures. At first the Kasauli institute was the only one in India, and drained the whole population of India. Then the Coonoor Institute was opened. In the time of Colonel Harvey and myself, the Kasauli Institute drained the whole of Northern India and Burma. Further, when one death from hydrophobia has occurred among a group of persons bitten, there is a natural tendency to send immediately all persons bitten by the same animal for treatment, no matter what interval has elapsed since they were bitten. In many such persons there is a great risk of developing hydrophobia; hence the inclusion of these cases tends to increase the mortality rate. In brief, lateness of arrival tends to increase the mortality rate. In Major McKendrick's time, the institute at Rangoon had been opened, and only the Assam cases came late. His figures were chiefly influenced by the second factor; i.e., the late arrival of persons bitten amongst whom one death from hydrophobia had occurred, i.e., persons at greater risk. In Major King's time, the Bombay and Shillong institutes had been opened, and the influence of distance had been practically eliminated; the curve shows a U form because all the badly bitten cases arrive early as they come from a short distance only, and the late cases are those only where a death from hydrophobia has occurred among the persons bitten; hence a selection occurs from natural causes, and the mortality rate is affected by these causes which have nothing to do with the treatment given, and therefore cannot be considered as a test for a cure.

TABLE II.

1923	7272	72	.99	3375	29	.8
1924	7852	61	.78	1834	1	.29
1925				489	7	1.43

Still a third way in which selection occurs from natural causes is that a treated population becomes increasingly diluted by persons who are not at risk. This is shewn in Table II, which gives on the one hand the percentage mortality at the Kasauli institute over a period of 25 years. On the other hand, the annual number of persons treated rose from 300 to 7,000. This means that with increasing knowledge of the facilities afforded by the institute, an increasing number of persons are treated and included in the figures who have been bitten by non-rabid animals. No medical man will take the risk of pronouncing whether the animal was or was not rabid, and so the patient is sent for treatment. In this way every Pasteur institute in the world comes to shew a steady diminution in its mortality rate, whether the treatment remains the same or not.

We see therefore that such natural selection may cause considerable variation in the population treated, as they are exposed to varying degrees of risk, and that this may greatly modify the results obtained.

Further, *exaggeration* is a not unnatural error among many medical men. One should make a careful note and written record of every case seen and treated; otherwise there is a great tendency to exaggerate the numbers seen. The ordinary honest person will unconsciously exaggerate about threefold, whilst others will multiply by ten or more. Whenever I hear a lecturer talking about the thousands of cases of this, that or the other disease which he has seen, without giving written chapter and verse for his statement, I always mentally take off the last digit of his figures. One's intentions may be strictly honourable, yet when one has seen a monotonous series of cases of a disease for years on end, there is a natural tendency to exaggerate. During the last five years I have collected written notes on approximately 500 cases of leucoderma, and, on an average, I have seen each patient about four times. Were I to trust merely to memory, I might easily think that I had seen about 2,000 cases. Such an error can only be prevented by making a written record of every case seen.

In addition to bias, the influences exerted by the law of random sampling, and exaggeration; still another factor comes into play, especially when dealing with protozoal diseases, and that is the risk of re-infection during the period that the patient is under observation. Little or no immunity is established in such cases, the specific drug given is eliminated from the body within a few days of cessation of treatment, and such persons may stand a very good chance of being re-infected when they return back to their own homes, and to the environment in which they contracted the original infection. I maintain that any tests to estimate the value of a cure for such diseases should not be carried out in an infective area, if this can possibly be avoided. Further, in connection with such diseases, there are certain seasons of the year when conditions are epidemic, such as the spring and early winter in malaria, and the monsoon months in kala-azar. A group of kala-azar patients discharged after treatment at the beginning of the winter would run but little chance of re-infection before the next rains commenced, whilst a similar group discharged during the early hot weather would run considerable risk during the monsoon which immediately follows.

Criteria in Testing the Cure.

We now come to the final test of the cure. The first point to ensure is that the composition of the two groups,—treated persons and untreated controls,—or persons treated by methods A and B respectively,—shall be *homogeneous*; otherwise the two groups will be dissimilar and the results not comparable with one another. The best way to ensure this is to place the patients as they arrive alternatively in groups A and B without selection. Even then, however, care must be exercised; otherwise by chance the first group may contain many early cases who have but little damage to the system, whilst the second group may contain many advanced cases which even the specific drug cannot cure, owing to irrevocable damage to essential tissues as the heart, etc.

Secondly, the number of persons in the two groups must be *sufficiently large*. Usually, in the common diseases, one tries to get 100 persons in each group, so as to get the percentage cure rate. A very common mistake and one which is a very bad one is to take small groups of three or six or nine patients, and elevate the results obtained into percentages. Three deaths out of six cases does *not* constitute a death rate of 50 per cent., as the next six cases may easily shew no deaths at all.

Having obtained figures from a sufficiently large and homogeneous population, mathematicians sometimes look upon the figures thus obtained as being perfectly accurate. One often hears the remark made that statistics can be made to shew the value of anything. In reality, figures only give us a guide to the formation of opinion. To interpret the results which we have obtained, we *must* have a full knowledge of the factors present, upon which I have dwelt. Having assessed their value and influence, and having carefully weighed up the pros and cons, we can then, and only then, pass our judgment upon the figures.

With regard to such factors, we must first eliminate the effects of *chance sampling*, by looking through the various data of our population and making certain that it is homogeneous. Usually, most observers do not give these essential data; they merely record so many cases treated or observed. If results are only slightly, and not significantly different, we can come to no conclusion; in such a case we must repeat the whole experiment again and see whether the slight difference is due to the remedy used, or whether it was the result of random sampling.

It is obvious, from what has already been said, that the differences between the two groups must be significant, and one beyond the range of chance sampling. Very few people appreciate what should constitute an *essential* or *significant difference*.

I may quote two examples to illustrate the meaning of a significant difference. In the case of a disease with a low mortality, say 1 to 5 per cent., if the cure is an efficacious one, it should eliminate almost the whole of this small mortality rate. On the other hand in a given Pasteur institute, the mortality rate among 3,000 persons treated in one year, may be 1.3 per cent.; the next year, among 4,000 persons treated, it may be 1.1 per cent. This difference is not significant, and upon investigation it will probably be found to depend upon the fact that the two populations compared are not similar to one another in some respect or other. The difference is not sufficient for the director of such an institute to claim that the treatment given in the second year was better than that given in the first year; some alteration in the composition of the two populations concerned will probably account for it.

Thirdly, we must understand what a *partial correlation* means. In many diseases the effect of rest, of improvement in the diet, of such drugs as act as tonics and raise the body resistance, is to improve the defence mechanism of the body. Such drugs do not act directly against the causative agent of the disease, but only inasmuch as they increase the patient's own natural powers of resistance. Thus we see that it would not be fair to compare the results of treatment of dysentery among in-patients with the results obtained among out-patients; the former have all the benefits of rest, nursing, and hospital diet, the latter do not.

Only when we have considered all these factors can we pass on to our judgment as to whether the difference between the two groups concerned is sufficient to warrant us in saying that the drug concerned is really a cure.

In passing, the case for rarer diseases may here be considered. When we are dealing with common diseases, it is easy to get large figures, and opinion can be based upon nothing else. But there are many rare diseases in which it would be impossible to obtain sufficient figures for a percentage in any one man's lifetime. In many such diseases, fortunately, we can rely upon the *chronicity of the infection*. To take an actual example, Plate 1 shows a case of a rare skin disease, *ichthyosis hystrix*, before and after treatment by the administration of desiccated thyroid gland substance.

were the result of only three weeks' treatment, whereas prior to treatment the disease had been slowly progressive in character. Similarly, I have recently had under treatment two patients whose lesions of the skin and mucous membranes corresponded to the clinical entity described as *xanthoma tuberosum multiplex*. The duration in one case had been sixteen years, in the other two years. Examination of films from the lesions of both patients shewed *Leishmania parasites*; and both cases cleared up completely with ten intravenous injections of von Heyden's Stibosan (471). In both these examples, the long prior duration and chronicity and progressive character of the disease, followed after treatment by immediate clearing of all lesions, is sufficient to enable one to say that the treatment adopted brought about cure. The rapidity of cure contrasts markedly with the slow progress and long duration of the diseases. Further, there are certain diseases that are at present known to be incurable and progressive in their course, such as paralysis agitans, tabes, and disseminated sclerosis. In such cases if one could arrest the disease entirely in only a few cases, it would be a sufficient guarantee that the drug had cured the disease; and that, in spite of the fact that whatever damage had previously occurred to the central nervous system would remain as a permanent injury, with its corresponding loss of function.

The Permanency of the Cure.

Proof that the cure is a permanent one lies in *time*. If the cure is a permanent one, the patient should continue for months or years to remain free from the disease, and in general good health. With regard to the value of the cure in the practice of medicine generally, the chief evidence of its value will rest in the *reduction in the incidence or in the mortality rate from the disease among the general population*. These two factors must always go hand in hand. Thus we know that the organic derivatives of arsenic introduced for the treatment of syphilis are curative from the point of view of immediate clearing up of clinical symptoms, and the change of the Wassermann reaction from positive to negative; but whether they really eradicate the

Plate 1.

Fig. 1.

A case of *Ichthyosis hystrix* kindly sent to me by Lt.-Colonel A. Denham White. The patient had suffered from the disease for 12 years. Photographs before and after three weeks' treatment with thyroid gland.

Fig. 2.

In this instance, the patient had had the disease for twelve years prior to treatment, and the results obtained

virus of syphilis from the body cannot yet be stated; if they do, then the incidence of tabes and of general

paralysis of the insane should shew a steady reduction in future years.

Cures and Non-Cures.

Even the universal acceptance of a cure as such by the medical profession in general cannot be taken as a guarantee that the cure is really efficacious. One must subject its claims to the most rigid scrutiny; one must study its effects on the mortality rate from the disease or its effects in the reduction of the incidence of relapses. Let us take three "cures" which are to-day universally accepted by the medical profession as such; viz., emetine, antivenene, and anti-rabic immunisation by vaccine.

(1) Emetine is a cure for amœbic abscess of the liver. In Chart I we see that, since the introduction of emetine in the treatment of amœbic abscess of the liver, the mortality rate from this disease amongst the British and

intestine, however, is a matter which must be held to be still *sub judice*; there can be no question of its great clinical value in amœbic dysentery, but whether it will totally eradicate the infection of the bowel is doubtful.

With regard to liver abscess, we have here an example of a proved and reliable cure.

(2) Calmette first introduced antivenene in about 1896, and, as far as I can find out from the literature, it first became a standard remedy for the treatment of snake-bite in India about 1900 or 1901. In Chart II is shewn graphically the number of deaths from snake-bite recorded by the Public Health Commissioner, India, for the years 1890 to 1923.

We see at once that, in spite of the introduction of antivenene, the total number of deaths from snake-bite per annum in this population has remained more or less

CHART I.

OBSERVATION.

Shows the total number of deaths from liver abscess in the British Army and families, Indian Army and Jails, from the years 1890 to 1924. Ipecacuanha treatment in 1906 by Sir Leonard Rogers for hepatitis, and Emetine in 1909.

Indian armies in India, and the jail population—figures for populations carefully observed by competent medical men over decades together—has fallen from 130 deaths in 1890 to 6 deaths in 1923. Not only is there abundant clinical evidence that emetine cures amœbic abscess of the liver; its effect upon the mortality from that disease in populations under skilled observation has been most striking.

the same; there has been no significant difference since the introduction of antivenene.

Why is this? Also why is it that antivenene appears to be an almost useless remedy in medical practice? We can easily prove in the laboratory that antivenene neutralises the venom of both the cobra and the Russell's viper, both *in vitro* and *in vivo*.

Major Knowles and I shewed in 1914 that, although

CHART II.

Shows the total deaths from snake-bite, and from hydrophobia in the British Army and families, Indian Army and Jails, from the years 1890 to 1924. Calmette's discovery of Antivenene in 1896. First Pasteur Institute of India opened at Kasauli, August 1900.

This result is also shewn graphically in Chart I, and the evidence is conclusive. Whether emetine is also an absolute cure for *Entamoeba histolytica* infection of the

1 c.c. of fresh antivenene will neutralise 1 mgm. of desiccated cobra venom *in vitro*, yet *in vivo* 1 c.c. will only neutralise 0.4 mgm. in experimental animals.

Further, antivenene steadily loses its potency when stored anywhere except in the ice chest. We further shewed that the average venom content of the glands of a cobra is about 207 mgms. of desiccated venom and the cobra can give at a good bite some two-thirds of this amount, an amount equivalent to about 138 mgms. of desiccated venom. To neutralise this amount of venom in the body, not the usually advocated dose of 20 to 30 c.c. of antivenene would be required, but some 200 to 400 c.c. administered intravenously. Such a dose may perhaps verge upon the toxic limit for the serum itself. The fact is that antivenene is a weak product, and that one of the most interesting problems in tropical medicine to-day is to discover some method of concentrating it. If a Professor of Biochemistry is ever sanctioned for the Calcutta School of Tropical Medicine I trust that he will give his attention to the question of trying to discover a really effective treatment for the bites of poisonous snakes.

(3) I do not desire here to enter into a discussion of the value or otherwise of anti-rabic treatment as practised in every Pasteur institute in India. The views of Colonel Harvey and myself, and the large volume of evidence in favour of such views, have previously been published. We regard the treatment as being only slightly, if at all, efficacious. In Chart II is shewn the mortality from hydrophobia among a population under skilled medical observation,—(the British and Indian armies and the jail population of India)—for the years 1890 to 1923. It will be seen that, despite the opening of one Pasteur institute after another, and despite the widespread issue of antirabic vaccine in the *mofussil* of recent years, the mortality rate has remained approximately constant over the whole 33 years. The difference is not significant.

In these three instances we have examples of

- (a) a cure which is undoubtedly efficacious,
- (b) a cure which is of value but which is administered in inadequate doses, and
- (c) a "cure," the value of which is doubtful.

The Relative Merits of Different, but Closely Allied Remedies.

We have seen how difficult it is to estimate the value of a cure. We may now pass to the consideration of an allied problem, where we have to decide upon the relative merits of two cures which give somewhat similar results. Here what we have really to decide is whether the difference between the results with the two cures is or is not significant. Since Ehrlich and Hatta discovered the value of *salvarsan* in syphilis we have seen a struggle going on in the medical profession between the advocates of this, that and the other organic arsenical preparation in the treatment of syphilis. At present we do not know whether any of these arsenical derivatives is or is not capable of exterminating the spirochæte of syphilis from the body system. A similar phenomenon is to-day occurring in India among the advocates of the several different preparations of pentavalent antimony for the treatment of kala-azar.

In such a connection I can only quote my experience in malaria with the different alkaloids of cinchona bark. The order of merit in which I found them to be efficacious in the treatment of benign tertian malaria was as follows:—

- Quinidine.
- Cinchonidine.
- Cinchona febrifuge (residual alkaloid).
- Quinine.
- Cinchonine.

My figures for some of the groups were small; also they had been subjected to the errors of random sampling. Further, a factor which was unexpectedly introduced was that, as soon as the Armistice of 1918 was signed, many of my patients, all of whom were British soldiers under treatment at Dagshai, being anxious to rejoin their units and be demobilised, started to buy quinine in the bazar and to take it in addition

to their standard treatment. I was only able to stop this practice by buying up all local stocks of quinine and storing them beyond their reach.

On the other hand, I found that these alkaloids differed in their effects upon gastric and peptic digestion, and in their pharmacological effects. They hindered gastric and peptic digestion in the following order, taking the most toxic first:—

- Cinchonine
- Quinidine
- Quinine
- Cinchonidine,

whilst the order in which they produced a fall of blood pressure on intravenous injection, taking the most active first, was as follows:—

- Quinidine.
- Quinine.
- Cinchonine.
- Cinchonidine.

From this it is obvious that, although quinidine has the most powerful parasitocidal action, yet on account of the fall in blood pressure which it produces, and its inhibition of gastric and peptic digestion, it cannot be the alkaloid of choice. The merits of the different alkaloids must be considered, not only with reference to their body activities as blood parasitocidal value, but also with reference to their effects upon blood pressure gastric and peptic digestion.

Similarly, when one is considering the relative merits of drugs with very similar therapeutic results, one must not only estimate the therapeutic efficacy of each, but their suitability for administration, their price for the patient, and their actions upon the body activities. A drug which seems the drug of choice from its parasitocidal action may not necessarily be the drug of election. One would naturally choose the least toxic drug, if its parasitocidal action is almost the same as the others.

* * * * *

The subject which I have introduced for discussion this evening is admittedly a difficult one. Yet it is very necessary that our ideas upon it should be clarified; that rational and critical enquiry should replace credulity.

Conclusions and Summary.

1. Cures may be of two kinds, permanent or temporary. In the latter condition, the causative agent of the disease is still present, but not in sufficient numbers to give rise to symptoms.

2. Permanent cures may occur with complete recovery of the tissues, or may be incomplete with impairment or loss of function.

3. In every test of a cure, the data of composition of the population tested should always be given as regards its important ætiological factors such as age, habits and customs, etc., since these factors may profoundly influence the course of the disease.

4. The two populations compared, those under test and the controls, should be similar in every respect; e.g., with regard to numbers, homogeneity, etc.

5. The percentage mortality or cure rate is obtained by observations on 100 individuals; not by elevating observations on digits into percentages.

6. A homogeneous population under test can only be secured by avoiding bias, and paying attention to the law of chance sampling.

7. The testing and control experiments should be carried out under identical conditions in order to avoid obtaining the results of only partial correlations. Also tests for a cure should if possible be carried out in non-infective areas, with regard to protozoal diseases, especially, in order to exclude the chances of re-infection.

8. Only differences between the two groups of a significant order should be considered; e.g., those outside the range of chance sampling, or partial correlation.

9. The permanency of a cure can only be tested by time, the continued well-being of the patients, and the effect of the introduction of the cure on the mortality rate for a given disease in the general population.

10. In cases of rare diseases, where large numbers of observations are not possible, one has to rely on diseases which shew chronicity before treatment, large mortality rate, and the rapid disappearance or arrest of the diseases when under treatment.

11. The relative value of a modification of treatment,—e.g., of the comparative value of the dry cord method and the dilution method of Hoghyes in anti-rabic treatment, or of the different pentavalent compounds of antimony in the treatment of kala-azar, can only be tested on a large scale. Consideration must also be paid to the relative toxicity to the body of the different compounds used, apart from their therapeutic value.
